QP (3) typically fall into the class of strictly convex parametric quadratic programs: the solution $U^*(\bar{x}_0)$, $X^*(\bar{x}_0)$ is unique and depends piecewise affinely and continuously on the parameter $\bar{x}_0$. Each affine piece of the solution map corresponds to one *active set* and is valid on one polyhedral *critical region* in parameter space. This observation forms the basis of *explicit MPC algorithms* which precompute the map $u_0^*(\bar{x}_0)$, but it can also be exploited in online algorithms for quadratic programming, which are the focus of this section.

We sketch the different ways of how to treat inequalities only for the condensed QP (3), but they can equally be applied in sparse QP algorithms that directly address (2). The optimal solution $U^*(\bar{x}_0)$ for a strictly convex QP (3) is – together with the corresponding vector of Lagrange multipliers, or dual variables $\lambda^*(\bar{x}_0) \in \mathbb{R}^m$ – uniquely characterized by the so-called Karush-Kuhn-Tucker (KKT) conditions, which we omit for brevity. There are three big families of solution algorithms for inequality-constrained QPs that differ in the way they treat inequalities: *active set methods*, *interior point methods*, and *gradient projection methods*.

Active Set Methods

The optimal solution of the QP is characterized by its *active set*, i.e., the set of inequality constraints (3b) that are satisfied with equality at this point. If one would know the active set for a given problem instance $\bar{x}_0$, it would be easy to find the solution. Active set methods work with guesses of the active set which they iteratively refine. In each iteration, they solve one linear system corresponding to a given guess of the active set. If the KKT conditions are satisfied, the optimal solution is found; if they are not, another division into active and inactive constraints needs to be tried. A crucial observation is that an existing factorization of the linear system can be reused to a large extent when only one constraint is added or removed from the guess of the active set. Many different active set strategies exist, three of which we mention: *Primal active set methods* first find a feasible point and then add or remove active constraints, always keeping the primal variables U feasible. Due to the difficulty of finding a

feasible point first, they are difficult to warmstart in the context of MPC optimization. *Dual active set strategies* always keep the dual variables λ positive. They can easily be warmstarted in the context of MPC. *Parametric* or *online active set strategies* ensure that all iterates stay primal and dual feasible and go on a straight line in parameter space from a solved QP problem to the current one, only updating the active set when crossing the boundary between critical regions, as implemented in the online QP solver qpOASES.

Active set methods are very competitive in practice, but their worst case complexity is not polynomial. They are often used together with the condensed QP formulation, for which each active set change is relatively cheap. This is particularly advantageous if an existing factorization can be kept between subsequent MPC optimization problems.

Interior Point Methods

Another approach is to replace the KKT conditions by a smooth approximation that uses a small positive parameter $\tau > 0$:

$$HU^* + G\bar{x}_0 + M^\top \lambda^* = 0, \quad (5a)$$

$$(d + K\bar{x}_0 + MU^*)_i \lambda_i^* + \tau = 0, \quad i = 1, \dots, m. \quad (5b)$$

These conditions form a smooth nonlinear system of equations that uniquely determines a primal dual solution $U^*(\bar{x}_0, \tau)$ and $\lambda^*(\bar{x}_0, \tau)$ in the interior of the feasible set. They are not equivalent to the KKT conditions, but for $\tau \rightarrow 0$, their solution tends to the exact QP solution. An interior point algorithm solves the system (5a) and (5b) by Newton's method. Simultaneously, the path parameter τ , that was initially set to a large value, is iteratively reduced, making the nonlinear set of equations a closer approximation of the original KKT system. In each Newton iteration, a linear system needs to be factored and solved, which constitutes the major computational cost of an interior point algorithm. For the condensed QP (3) with dense matrices H, M , the cost per Newton iteration is of order $O(N^3)$. But the interior point algorithm can also

be applied to the uncondensed sparse QP (2), in which case each iteration has a runtime of order $O(N)$. In practice, for both cases, 10–30 Newton iterations usually suffice to obtain very accurate solutions. As an interior point method needs always to start with a high value of τ and then reduces it during the iterations, warmstarting is of minor benefit. There exist efficient code generation tools that export convex interior point solvers as plain C-code such as CVXGEN and FORCES.

Gradient Projection Methods

Gradient projection methods do not need to factorize any matrix but only evaluate the gradient of the objective function $HU^{[k]} + G\bar{x}_0$ in each iteration. They can only be implemented efficiently if the feasible set is a simple set in the sense that a projection $P(U)$ on this set is very cheap to compute, as, e.g., for upper and lower bounds on the variables U , and if we know an upper bound $L_H > 0$ on the eigenvalues of the Hessian H . The simple gradient projection algorithm starts with an initialization $U^{[0]}$ and proceeds as follows:

$$U^{[k+1]} = P \left(U^{[k]} - \frac{1}{L_H} (HU^{[k]} + G\bar{x}_0) \right).$$

An improved version of the gradient projection algorithm is called the *optimal* or *fast gradient method* and has probably the best possible iteration complexity of all gradient type methods. All variants of gradient projection algorithms are easy to warmstart. Though they are not as versatile as active set or interior point methods, they have short code sizes and can offer advantages on embedded computational hardware, such as the code generated by the tool FIORDOS.

Optimization Algorithms for Nonlinear MPC

When the dynamic system $x_{i+1} = f(x_i, u_i)$ is not affine, the optimal control problem (1) is non-convex, and we speak of a nonlinear

MPC (NMPC) problem. NMPC optimization algorithms only aim at finding a locally optimal solution of this problem, and they usually do it in a Newton-type framework. For ease of notation, we summarize problem (1) in the form of a general nonlinear programming problem (NLP):

$$\begin{aligned} &\text{minimize} && \Phi(X, U) && (6a) \\ &&& X, U \end{aligned}$$

$$\text{subject to} \quad G_{\text{eq}}(X, U, \bar{x}_0) = 0, \quad (6b)$$

$$G_{\text{ineq}}(X, U) \leq 0. \quad (6c)$$

Let us first discuss a fundamental choice that regards the problem formulation and number of optimization variables.

Simultaneous vs. Sequential Formulation

When an optimization algorithm addresses problem (6) iteratively, it works intermediately with nonphysical, infeasible trajectories that violate the system constraints (6b). Only at the optimal solution the constraint residual is brought to zero and a physical simulation is achieved. We speak of a *simultaneous approach* to optimal control because the algorithm solves the simulation and the optimization problems simultaneously. Variants of this approach are *direct discretization* or *direct multiple shooting*.

On the other hand, the equality constraints (6b) could easily be eliminated by a nonlinear forward simulation for given initial value $\bar{x}_0$ and control trajectory U , similar to condensing in linear MPC. Such a forward simulation generates a state trajectory $X_{\text{sim}}(\bar{x}_0, U)$ such that for the given value of $\bar{x}_0$, U the equality constraints (6b) are automatically satisfied: $G_{\text{eq}}(X_{\text{sim}}(\bar{x}_0, U), U, \bar{x}_0) = 0$. Inserting this map into the NLP (6) allows us to formulate an equivalent optimization problem with a reduced variable space:

$$\begin{aligned} &\text{minimize} && \Phi(X_{\text{sim}}(\bar{x}_0, U), U) && (7a) \\ &&& U \end{aligned}$$

$$\text{subject to} \quad G_{\text{ineq}}(X_{\text{sim}}(\bar{x}_0, U), U) \leq 0. \quad (7b)$$

When solving this reduced problem with an iterative optimization algorithm, we sequentially simulate and optimize the system, and we speak of the *sequential approach* to optimal control.

The sequential approach has a lower dimensional variable space and is thus easier to use with a black-box NLP solver. On the other hand, the simultaneous approach leads to a sparse NLP and is better able to deal with unstable nonlinear systems. In the remainder of this section, we thus only discuss the specific structure of the simultaneous approach.

Newton-Type Optimization

In order to simplify notation further, we summarize and reorder all optimization variables U and X in a vector $V = [x_0^\top, u_0^\top, \dots, x_{N-1}^\top, u_{N-1}^\top, x_N^\top]^\top$ and use the same problem function names as in (6) also with the new argument V .

As in the section on linear MPC, we can introduce multipliers Y for the equalities and λ for the inequalities and define the Lagrangian

$$L(V, Y, \lambda) = \Phi(V) + Y^\top G_{\text{eq}}(V, \bar{x}_0) + \lambda^\top G_{\text{ineq}}(V). \quad (8)$$

All Newton-type optimization methods try to find a point satisfying the KKT conditions by using successive linearizations of the problem functions and Lagrangian. For this aim, starting with an initial guess $(V^{[0]}, Y^{[0]}, \lambda^{[0]})$, they generate sequences of primal-dual iterates $(V^{[k]}, Y^{[k]}, \lambda^{[k]})$.

An observation that is crucial for the efficiency of all NMPC algorithms is that the Hessian of the Lagrangian is at a current iterate given by a matrix of the form

$$\nabla_V^2 L(\cdot) = \begin{bmatrix} Q_0^{[k]} & S_0^{[k]} & & & \\ S_0^{[k],\top} & R_0^{[k]} & & & \\ & & Q_1^{[k]} & S_1^{[k]} & \\ & & S_1^{[k],\top} & R_1^{[k]} & \\ & & & & \ddots \\ & & & & & P^{[k]} \end{bmatrix}.$$

This block sparse matrix structure makes it possible to use in each Newton-type iteration the same sparsity-exploiting linear algebra techniques as outlined in section “[Convex Optimization for Linear MPC](#)” for the linear MPC problem.

Major differences exist on how to treat the inequality constraints, and the two big families of Newton-type optimization methods are *sequential quadratic programming (SQP)* methods and *nonlinear interior point (NIP)* methods.

Sequential Quadratic Programming (SQP)

A first variant to iteratively solve the KKT system is to linearize all nonlinear functions at the current iterate $(V^{[k]}, Y^{[k]}, \lambda^{[k]})$ and to find a new solution guess from the solution of a quadratic program (QP):

$$\underset{V}{\text{minimize}} \quad \Phi_{\text{quad}}(V; V^{[k]}, Y^{[k]}, \lambda^{[k]}) \quad (9a)$$

$$\text{subject to} \quad G_{\text{eq,lin}}(V, \bar{x}_0; V^{[k]}) = 0, \quad (9b)$$

$$G_{\text{ineq,lin}}(V; V^{[k]}) \leq 0. \quad (9c)$$

Here, the subindex “lin” in the constraints $G_{\cdot,\text{lin}}$ expresses that a first-order Taylor expansion at $V^{[k]}$ is used, while the QP objective is given by $\Phi_{\text{quad}}(V; V^{[k]}, Y^{[k]}, \lambda^{[k]}) = \Phi_{\text{lin}}(V; V^{[k]}) + \frac{1}{2}(V - V^{[k]})^\top \nabla_V^2 L(\cdot)(V - V^{[k]})$. Note that the QP has the same sparsity structure as the QP (2) resulting from linear MPC, with the only difference that all matrices are now time varying over the MPC horizon. In the case that the Hessian matrix is positive semi-definite, this QP is convex so that global solutions can be found reliably with any of the methods from section “[Convex Optimization for Linear MPC](#).” The solution of the QP along with the corresponding constraint multipliers gives the next SQP iterate $(V^{[k+1]}, Y^{[k+1]}, \lambda^{[k+1]})$. Apart from the presented “exact Hessian” SQP variant, which has quadratic convergence speed, several other SQP variants exist, which make use of other Hessian approximations. A particularly useful Hessian approximation for NMPC is possible if the original objective function $\Phi(V)$ is convex quadratic, and the resulting SQP variant is called

the *generalized Gauss-Newton* method. In this case, one can just use the original objective as cost function in the QP (9a), resulting in convex QP subproblems and (often fast) linear convergence speed.

Nonlinear Interior Point (NIP) Method

In contrast to SQP methods, an alternative way to address the solution of the KKT system is to replace the last nonsmooth KKT conditions by a smooth nonlinear approximation, with $\tau > 0$:

$$\nabla_V L(V^*, Y^*, \lambda^*) = 0 \quad (10a)$$

$$G_{\text{eq}}(V^*, \bar{x}_0) = 0 \quad (10b)$$

$$G_{\text{ineq},i}(V^*) \lambda_i^* + \tau = 0, \quad i = 1, \dots, m. \quad (10c)$$

We summarize all variables in a vector $W = [V^\top, Y^\top, \lambda^\top]^\top$ and summarize the above set of equations as

$$G_{\text{NIP}}(W, \bar{x}_0, \tau) = 0. \quad (11)$$

The resulting root finding problem is then solved with Newton's method, for a descending sequence of path parameters $\tau^{[k]}$. The NIP method proceeds thus exactly as in an interior point method for convex problems, with the only difference that it has to re-linearize all problem functions in each iteration. An excellent software implementation of the NIP method is given in the form of the code IPOPT.

Continuation Methods and Tangential Predictors

In nonlinear MPC, a sequence of OCPs with different initial values $\bar{x}_0^{[0]}, \bar{x}_0^{[1]}, \bar{x}_0^{[2]}, \dots$ is solved. For the transition from one problem to the next, it is beneficial to take into account the fact that the optimal solution $W^*(\bar{x}_0)$ depends almost everywhere differentiably on $\bar{x}_0$. The concept of a continuation method is most easily explained in the context of an NIP method with fixed path parameter $\bar{\tau} > 0$. In this case, the solution $W^*(\bar{x}_0, \bar{\tau})$ of the smooth root finding problem $G_{\text{NIP}}(W^*(\bar{x}_0, \bar{\tau}), \bar{x}_0, \bar{\tau}) = 0$ from Eq. (11) is

smooth with respect to $\bar{x}_0$. This smoothness can be exploited by making use of a *tangential predictor* in the transition from one value of $\bar{x}_0$ to another. Unfortunately, the interior point solution manifold is strongly nonlinear at points where the active set changes, and the tangential predictor is not a good approximation when we linearize at such points.

Generalized Tangential Predictor and Real-Time Iterations

In fact, the true NLP solution is not determined by a smooth root finding problem (10a)–(10c) but by the (nonsmooth) KKT conditions. The solution manifold has smooth parts when the active set does not change, but non-differentiable points occur whenever the active set changes. We can deal with this fact naturally in an SQP framework by solving one QP of form (9) in order to generate a tangential predictor that is also valid in the presence of active set changes. In the extreme case that only one such QP is solved per sampling time, we speak of a *real-time iteration (RTI)* algorithm. The computations in each iteration can be subdivided into two phases, the *preparation phase*, in which the derivatives are computed and the QP is condensed, and the *feedback phase*, which only starts once $\bar{x}_0^{[k+1]}$ becomes available and in which only a condensed QP of form (3) is solved, minimizing the feedback delay. This NMPC algorithm can be generated as plain C-code, e.g., by the tool ACADO. Another class of real-time NMPC algorithms based on a continuation method can be generated by the tool AutoGenU.

Abstract

Structured output feedback controller synthesis is an exciting recent concept in modern control design, which bridges between theory and practice in so far as it allows for the first time to apply sophisticated mathematical

design paradigms like H_∞ - or H_2 -control within control architectures preferred by practitioners. The new approach to structured H_∞ -control, developed by the authors during the past decade, is rooted in a change of paradigm in the synthesis algorithms. Structured design is no longer based on solving algebraic Riccati equations or matrix inequalities. Instead, optimization-based design techniques are required. In this essay we indicate why structured controller synthesis is central in modern control engineering. We explain why non-smooth optimization techniques are needed to compute structured control laws, and we point to software tools which enable practitioners to use these new tools in high-technology applications.

Introduction

In the modern high-technology field, control engineers usually face a large variety of concurring design specifications such as noise or gain attenuation in prescribed frequency bands, damping, decoupling, constraints on settling time or risetime, and much else. In addition, as plant models are generally only approximations of the true system dynamics, control laws have to be robust with respect to uncertainty in physical parameters or with regard to un-modeled high-frequency phenomena. Not surprisingly, such a plethora of constraints presents a major challenge for controller tuning, due not only to the ever growing number of such constraints but also because of their very different provenience.

The steady increase in plant complexity is exacerbated by the quest that regulators should be as simple as possible, easy to understand and to tune by practitioners, convenient to hardware

implement, and generally available at low cost. These practical constraints highlight the limited use of Riccati- or LMI-based controllers, and they are the driving force for the implementation of *structured* control architectures. On the other hand, this means that hand-tuning methods have to be replaced by rigorous algorithmic optimization tools.

Structured Controllers

Before addressing specific optimization techniques, we recall some basic terminology for control design problems with structured controllers. The plant model P is described as

$$P : \begin{cases} \dot{x}_P = A x_P + B_1 w + B_2 u \\ z = C_1 x_P + D_{11} w + D_{12} u \\ y = C_2 x_P + D_{21} w + D_{22} u \end{cases} \quad (1)$$

where $A, B_1, \dots$ are real matrices of appropriate dimensions, $x_P \in \mathbb{R}^{n_P}$ is the state, $u \in \mathbb{R}^{n_u}$ the control, $y \in \mathbb{R}^{n_y}$ the measured output, $w \in \mathbb{R}^{n_w}$ the exogenous input, and $z \in \mathbb{R}^{n_z}$ the regulated output. Similarly, the sought output feedback controller K is described as

$$K : \begin{cases} \dot{x}_K = A_K x_K + B_K y \\ u = C_K x_K + D_K y \end{cases} \quad (2)$$

with $x_K \in \mathbb{R}^{n_K}$ and is called *structured* if the (real) matrices A_K, B_K, C_K, D_K depend smoothly on a design parameter $\mathbf{x} \in \mathbb{R}^n$, referred to as the vector of tunable parameters. Formally, we have differentiable mappings

$$\begin{aligned} A_K &= A_K(\mathbf{x}), B_K = B_K(\mathbf{x}), C_K = C_K(\mathbf{x}), \\ D_K &= D_K(\mathbf{x}), \end{aligned}$$

and we abbreviate these by the notation $K(\mathbf{x})$ for short to emphasize that the controller is structured with $\mathbf{x}$ as tunable elements. A structured controller synthesis problem is then an optimization problem of the form

Optimization-Based Control Design Techniques and Tools, Fig. 1 Black-box full-order controller K on the left, structured 2-DOF control architecture with $K = \text{diag}(K_1, K_2)$ on the right

$$\begin{aligned} & \text{minimize } \|T_{wz}(P, K(\mathbf{x}))\| \\ & \text{subject to } K(\mathbf{x}) \text{ closed-loop stabilizing} \quad (3) \\ & K(\mathbf{x}) \text{ structured, } \mathbf{x} \in \mathbb{R}^n \end{aligned}$$

where $T_{wz}(P, K) = \mathcal{F}_\ell(P, K)$ is the lower feed-back connection of (1) with (2) as in Fig. 1 (left), also called the linear fractional transformation (Zhou et al. 1996). The norm $\|\cdot\|$ stands for the H_∞ -norm, the H_2 -norm, or any other system norm, while the optimization variable $\mathbf{x} \in \mathbb{R}^n$ regroups the tunable parameters in the design.

Standard examples of structured controllers $K(\mathbf{x})$ include realizable PIDs, observer-based, reduced-order, or decentralized controllers, which in state space are expressed as:

$$\begin{aligned} & \left[\begin{array}{cc|c} 0 & 0 & 1 \\ 0 & -1/\tau & -k_D/\tau \\ \hline k_I & 1/\tau & k_P + k_D/\tau \end{array} \right], \\ & \left[\begin{array}{c|c} A - B_2K_c - K_fC_2 & K_f \\ \hline -K_c & 0 \end{array} \right], \quad \left[\begin{array}{c|c} A_K & B_K \\ \hline C_K & D_K \end{array} \right], \\ & \left[\begin{array}{c|c} \text{diag}(A_{K_1}, \dots, A_{K_q}) & \text{diag}(B_{K_1}, \dots, B_{K_q}) \\ \hline \text{diag}(C_{K_1}, \dots, C_{K_q}) & \text{diag}(D_{K_1}, \dots, D_{K_q}) \end{array} \right]. \end{aligned}$$

In the case of a PID, the tunable parameters are $\mathbf{x} = (\tau, k_P, k_I, k_D)$; for observer-based controllers, $\mathbf{x}$ regroups the estimator and state-feedback gains (K_f, K_c); for reduced order controllers $n_K < n_P$, the tunable parameters $\mathbf{x}$ are the $n_K^2 + n_K n_y + n_K n_u + n_y n_u$ unknown entries in (A_K, B_K, C_K, D_K) ; and in the decentralized form, $\mathbf{x}$ regroups the unknown entries in $A_{K_1}, \dots, D_{K_q}$. In contrast, full-order controllers have the maximum number $N = n_P^2 + n_P n_y + n_P n_u + n_y n_u$ of degrees

of freedom and are referred to as unstructured or as *black-box* controllers.

More sophisticated controller structures $K(\mathbf{x})$ arise from architectures like a 2-DOF control arrangement with feedback block K_2 and a set-point filter K_1 as in Fig. 1 (right). Suppose K_1 is the 1st-order filter $K_1(s) = a/(s + a)$ and K_2 the PI feedback $K_2(s) = k_P + k_I/s$. Then the transfer T_{ry} from r to y can be represented as the feedback connection of P and $K(\mathbf{x}, s)$ with

$$P = \left[\begin{array}{c|cc} A & 0 & B \\ \hline C & 0 & D \\ 0 & I & 0 \\ \hline -C & I & -D \end{array} \right],$$

$$K(\mathbf{x}, s) = \begin{bmatrix} K_1(a, s) & K_2(k_P, k_I, s) \end{bmatrix},$$

and gathering tunable elements in $\mathbf{x} = (a, k_P, k_I)$.

In much the same way, arbitrary multi-loop interconnections of fixed-model elements with tunable controller blocks $K_i(\mathbf{x})$ can be rearranged as in Fig. 2, so that $K(\mathbf{x})$ captures all tunable blocks in a decentralized structure general enough to cover most engineering applications.

The structure concept is equally useful to deal with the second central challenge in control design: *system uncertainty*. The latter may be handled with μ -synthesis techniques (Stein and Doyle 1991) if a parametric uncertain model is available. A less ambitious but often more practical alternative consists in optimizing the structured controller $K(\mathbf{x})$ against a finite set of plants $P^{(1)}, \dots, P^{(M)}$ representing model variations due to uncertainty, aging, sensor and actuator breakdown, un-modeled dynamics, in tandem

Optimization-Based Control Design Techniques and Tools,

Fig. 2 Synthesis of $K = \text{diag}(K_1, \dots, K_N)$ against multiple requirements or models $P^{(1)}, \dots, P^{(M)}$. Each $K_i(x)$ can be structured

with the robustness and performance specifications. This is again formally covered by Fig. 2 and leads to a multi-objective constrained optimization problem of the form

$$\begin{aligned} \text{minimize } f(\mathbf{x}) &= \max_{k \in \text{SOFT}, i \in I_k} \|T_{w_i z_i}^{(k)}(K(\mathbf{x}))\| \\ \text{subject to } g(\mathbf{x}) &= \max_{k \in \text{HARD}, j \in J_k} \|T_{w_j z_j}^{(k)}(K(\mathbf{x}))\| \leq 1 \\ &K(\mathbf{x}) \text{ structured and stabilizing} \\ &\mathbf{x} \in \mathbb{R}^n \end{aligned} \quad (4)$$

where $T_{w_i z_i}^{(k)}$ denotes the i th closed-loop robustness or performance channel $w_i \rightarrow z_i$ for the k -th plant model $P^{(k)}$. SOFT and HARD denote index sets taken over a finite set of specifications, say in $\{1, \dots, M\}$. The rationale of (4) is to minimize the worst-case cost of the soft constraints $\|T_{w_i z_i}^{(k)}\|$, $k \in \text{SOFT}$, while enforcing the hard constraints $\|T_{w_j z_j}^{(k)}\| \leq 1$, $k \in \text{HARD}$, which prevail over soft ones and are mandatory. In addition to local optimization (4), the problem can undergo a global optimization step in order to prove global stability and performance of the design, see Ravanbod et al. (2017) and Apkarian et al. (2015a, b).

Optimization Techniques Over the Years

During the late 1990s, the necessity to develop design techniques for structured regulators $K(\mathbf{x})$ was recognized (Fares et al. 2001), and the limitations of synthesis methods based on algebraic Riccati equations or linear matrix inequalities

(LMIs) became evident, as these techniques cannot provide structured controllers needed in practice. The lack of appropriate synthesis techniques for structured $K(\mathbf{x})$ led to the unfortunate situation, where sophisticated approaches like the H_∞ paradigm developed by academia since the 1980s could not be brought to work for the design of those controller structures $K(\mathbf{x})$ preferred by practitioners. Design engineers had to continue to rely on heuristic and ad hoc tuning techniques, with only limited scope and reliability. As an example, post-processing to reduce a black-box controller to a practical size is prone to failure. It may at best be considered a fill-in for a rigorous design method which directly computes a reduced-order controller. Similarly, hand-tuning of the parameters $\mathbf{x}$ remains a puzzling task because of the loop interactions and fails as soon as complexity increases.

In the late 1990s and early 2000s, a change of methods was observed. Structured H_2 - and H_∞ -synthesis problems (3) were addressed by bilinear matrix inequality (BMI) optimization, which used local optimization techniques based on the augmented Lagrangian method (Fares et al. 2001; Noll et al. 2004; Kocvara and Stingl 2003; Noll 2007), sequential semidefinite programming methods (Fares et al. 2002; Apkarian et al. 2003), and non-smooth methods for BMIs (Noll et al. 2009; Lemaréchal and Oustry 2000). However, these techniques were based on the bounded real lemma or similar matrix inequalities and were therefore of limited success due to the presence of Lyapunov variables, i.e., matrix-valued unknowns, whose dimension grows quadratically in $n_P + n_K$ and represents the bottleneck of that approach.

The epoch-making change occurs with the introduction of non-smooth optimization techniques (Noll and Apkarian 2005; Apkarian and Noll 2006b,c, 2007) to programs (3) and (4). Today non-smooth methods have superseded matrix inequality-based techniques and may be considered the state of art as far as realistic applications are concerned. The transition took almost a decade.

Alternative control-related local optimization techniques and heuristics include the gradient sampling technique of Burke et al. (2005), and other derivative-free optimization techniques as in Kolda et al. (2003) and Apkarian and Noll (2006a), particle swarm optimization, see Oi et al. (2008) and references therein, and also evolutionary computation techniques (Lieslehto 2001). All these classes do not exploit derivative information and rely on function evaluations only. They are therefore applicable to a broad variety of problems including those where function values arise from complex numerical simulations. The combinatorial nature of these techniques, however, limits their use to small problems with a few tens of variable. More significantly, these methods often lack a solid convergence theory. In contrast, as we have demonstrated over recent years (Apkarian and Noll 2006b; Noll et al. 2008; Apkarian et al. 2016, 2018), specialized non-smooth techniques are highly efficient in practice, are based on a sophisticated convergence theory, are capable of solving medium-size problems in a matter of seconds, and are still operational for large-size problems with several hundreds of states.

Non-smooth Optimization Techniques

The benefit of the non-smooth casts (3) and (4) lies in the possibility to avoid searching for Lyapunov variables, a major advantage as their number $(n_P + n_K)^2/2$ usually largely dominates n , the number of true decision parameters $\mathbf{x}$. Lyapunov variables do still occur implicitly in the function evaluation procedures, but this has no harmful effect for systems up to several hundred

states. In abstract terms, a non-smooth optimization program has the form

$$\begin{aligned} & \text{minimize } f(\mathbf{x}) \\ & \text{subject to } g(\mathbf{x}) \leq 0 \\ & \mathbf{x} \in \mathbb{R}^n \end{aligned} \quad (5)$$

where $f, g : \mathbb{R}^n \rightarrow \mathbb{R}$ are locally Lipschitz functions and are easily identified from the cast in (4).

In the realm of convex optimization, non-smooth programs are conveniently addressed by so-called bundle methods, introduced in the late 1970s by Lemaréchal (1975). Bundle methods are used to solve difficult problems in integer programming or in stochastic optimization via Lagrangian relaxation. Extensions of the bundling technique to non-convex problems like (3) or (4) were first developed in Apkarian and Noll (2006b,c, 2007), Apkarian et al. (2008), and Noll et al. (2009) and, in more abstract form, in Noll et al. (2008). Recently, we also extended bundle techniques to the trust-region framework (Apkarian et al. 2016, 2018; Apkarian and Noll 2018), which leads to the first extension of the classical trust-region method to non-differential optimization supported by a valid convergence theory.

Figure 3 shows a schematic view of a non-convex bundle method consisting of a descent-step generating inner loop (yellow block) comparable to a line search in smooth optimization, embedded into the outer loop (blue box), where serious iterates are processed, stopping criteria are applied, and the acceptance rules of traditional trust-region techniques are assured. At the core of the interaction between inner and outer loop is the management of the proximity control parameter τ , which governs the stepsize $\|\mathbf{x} - \mathbf{y}^k\|$ between trial steps $\mathbf{y}^k$ at the current serious iterate $\mathbf{x}$. Similar to the management of a trust-region radius or of the step size in a line search, proximity control allows to force shorter trial steps if agreement of the local model with the true objective function is poor and allows larger steps if agreement is satisfactory.

Oracle-based bundle methods traditionally assure global convergence in the sense of

Optimization-Based Control Design Techniques and Tools, Fig. 3 Flow chart of proximity control bundle algorithm

subsequences under the sole hypothesis that for every trial point x , the function value $f(x)$ and one Clarke subgradient $\phi \in \partial f(x)$ are provided. In automatic control applications, it is as a rule possible to provide more specific information, which may be exploited to speed up convergence (Apkarian and Noll 2006b).

Computing function value and gradients of the H_2 -norm $f(x) = \|T_{wz}(P, K(x))\|_2$ requires essentially the solution of two Lyapunov equations of size $n_P + n_K$; see Apkarian et al. (2007). For the H_∞ -norm, $f(x) = \|T_{wz}(P, K(x))\|_\infty$, function evaluation is based on the Hamiltonian algorithm of Benner et al. (2012) and Boyd et al. (1989). The Hamiltonian matrix is of size $2(n_P + n_K)$, so that function evaluations may be costly for very large plant state dimension ($n_P > 500$), even though the number of outer loop iterations of the bundle algorithm is not affected by a large n_P and generally relates to n , the dimension of x .

The additional cost for subgradient computation for large n_P is relatively cheap as it relies on linear algebra (Apkarian and Noll 2006b). Function and subgradient evaluations for H_∞ and H_2 norms are typically obtained in $\mathcal{O}((n_P + n_K)^3)$ flops.

Computational Tools

Our non-smooth optimization methods became available to the engineering community since 2010 via the MATLAB Robust Control Toolbox (Robust Control Toolbox 4.2 2012; Gahinet and Apkarian 2011). Routines HINFSTRUCT, LOOPTUNE, and SYSTUNE are versatile enough to define and combine tunable blocks $K_i(x)$, to build and aggregate multiple models and design requirements on $T_{wz}^{(k)}$ of different nature, and to provide suitable validation tools. Their

implementation was carried out in cooperation with P. Gahinet (MathWorks). These routines further exploit the structure of problem (4) to enhance efficiency; see Apkarian and Noll (2007) and Apkarian and Noll (2006b).

It should be mentioned that design problems with multiple hard constraints are inherently complex and generally NP-hard, so that exhaustive methods fail even for small- to medium-size problems. The principled decision made in Apkarian and Noll (2006b), and reflected in the MATLAB tools, is to rely on local optimization techniques instead. This leads to weaker convergence certificates but has the advantage to work successfully in practice. In the same vein, in (4) it is preferable to rely on a mixture of soft and hard requirements, for instance, by the use of exact penalty functions (Noll and Apkarian 2005). Key features implemented in the mentioned MATLAB routines are discussed in Apkarian (2013), Gahinet and Apkarian (2011), and Apkarian and Noll (2007).

Applications

Design of a feedback regulator is an interactive process, in which tools like SYSTUNE, LOOPTUNE, or HINFSTRUCT support the designer in various ways. In this section we illustrate their enormous potential by showing that even infinite-dimensional systems may be successfully addressed by these tools. For a plethora of design examples for real-rational systems including parametric and complex dynamic uncertainty, we refer to Ravanbod et al. (2017), Apkarian et al. (2015a, 2016, 2018), and Apkarian and Noll (2018). For recent applications of our tools in real-world applications, see also Falcoz et al. (2015), where it is in particular explained how HINFSTRUCT helped in 2014 to save the Rosetta mission. Another important application of HINFSTRUCT is the design of the atmospheric flight pilot for the ARIANE VI launcher by the ArianeGroup (Ganet-Schoeller et al. 2017).

Illustrative Example

We discuss boundary control of a wave equation with anti-stable damping,

$$\begin{aligned}x_{tt}(\xi, t) &= x_{\xi\xi}(\xi, t), \quad t \geq 0, \xi \in [0, 1] \\x_{\xi}(0, t) &= -qx_t(0, t), \quad q > 0, q \neq 1 \quad (6) \\x_{\xi}(1, t) &= u(t).\end{aligned}$$

where notations x_y and x_{yy} stand for partial first- and second-order derivatives of x with respect to y , respectively. In (6), $x(\cdot, t)$, $x_t(\cdot, t)$ is the state; the control applied at the boundary $\xi = 1$ is $u(t)$, and we assume that the measured outputs are

$$\begin{aligned}y_1(t) &= x(0, t), \quad y_2(t) = x(1, t), \\y_3(t) &= x_t(1, t).\end{aligned} \quad (7)$$

The system has been discussed previously in Smyshlyaev and Krstic (2009), Fridman (2014), and Bresch-Pietri and Krstic (2014) and has been proposed for the control of slip-stick vibrations in drilling devices (Saldivar et al. 2013). Here measurements y_1, y_2 correspond to the angular positions of the drill string at the top and bottom level, and y_3 measures angular speed at the top level, while control corresponds to a reference velocity at the top. The friction characteristics at the bottom level are characterized by the parameter q , and the control objective is to maintain a constant angular velocity at the bottom.

Similar models have been used to control pressure fields in duct combustion dynamics; see DeQueiroz and Rahn (2002). The challenge in (6) and (7) is to design implementable controllers despite the use of an infinite-dimensional system model.

The transfer function of (6) is obtained from

$$G(\xi, s) = \frac{x(\xi, s)}{u(s)} = \frac{1}{s} \cdot \frac{(1-q)e^{s\xi} + (1+q)e^{-s\xi}}{(1-q)e^s - (1+q)e^{-s}},$$

which in view of (7) leads to $G(s)^T = [G_1 \ G_2 \ G_3] = [G(0, s) \ G(1, s) \ sG(1, s)]$.

Putting G in feedback with the controller $K_0 = [0 \ 0 \ 1]$ leads to $\widehat{G} = G/(1 + G_3)$, where

Optimization-Based Control Design Techniques and Tools, Fig. 4 Stability of the closed-loop ($\tilde{G} + \Phi, K$) is equivalent to stability of the closed-loop ($\tilde{G}$, feedback(K, Φ)). See also Moelja and Meinsma (2003)

$$\hat{G}(s) = \begin{bmatrix} \frac{1}{s(1-q)} \\ \frac{1+Q}{2s} \\ \frac{1}{2} \end{bmatrix} + \begin{bmatrix} -\frac{1-e^{-s}}{s(1-q)} \\ -\frac{Q(1-e^{-2s})}{2s} \\ \frac{Q}{2}e^{-2s} \end{bmatrix} \\ =: \tilde{G}(s) + \Phi(s), \quad (8)$$

where $Q = (1+q)/(1-q)$.

Here $\tilde{G}$ is real-rational and unstable, while Φ is stable but infinite dimensional. The latter follows from the fact that $\frac{1-e^{-s}}{s}$ and $\frac{1-e^{-2s}}{2s}$ are stable transfert functions as clarified by series expansions. Now we use the fact that stability of the closed loop ($\tilde{G} + \Phi, K$) is equivalent to stability of the loop ($\tilde{G}$, feedback(K, Φ)) upon defining feedback(M, N) := $M(I + NM)^{-1}$. The loop transformation is explained in Fig. 4.

Using (8) we construct a finite-dimensional structured controller $\tilde{K} = \tilde{K}(x)$ which stabilizes $\tilde{G}$. The controller K stabilizing $\hat{G}$ in (8) is then recovered from $\tilde{K}$ through the equation $\tilde{K} = \text{feedback}(K, \Phi)$, which when inverted gives $K = \text{feedback}(\tilde{K}, -\Phi)$. The overall controller for (6) is $K^* = K_0 + K$, and since along with K only delays appear in Φ , the controller K^* is implementable.

Construction of $\tilde{K}$ uses SYSTUNE with pole placement via TuningGoal.Poles, imposing that closed-loop poles have a minimum decay of 0.9, minimum damping of 0.9, and a maximum frequency of 4.0. The controller structure is chosen as static, so that $x \in \mathbb{R}^3$. A simulation with K^* is shown in Fig. 5 (bottom), and some acceleration over the backstepping controller from Bresch-Pietri and Krstic (2014) (top) is observed.

Optimization-Based Control Design Techniques and Tools, Fig. 5 Wave equation. Simulations for K obtained by backstepping control (top) (Bresch-Pietri and Krstic 2014) and $K^* = K_0 + K$ obtained by optimizing feedback($\tilde{G}, \tilde{K}$) via SYSTUNE (bottom). Both controllers are ∞ -dimensional but implementable

Gain-Scheduling Control

Our last study is when the parameter $q \geq 0$ is uncertain or allowed to vary in time with sufficiently slow variations as in Shamma and Athans (1990). We assume that a nominal $q_0 > 0$ and an uncertain interval $[q, \bar{q}]$ with $q_0 \in (q, \bar{q})$ and $1 \notin [q, \bar{q}]$ are given.

The following scheduling scenarios, all leading to implementable controllers, are possible: (a) computing a nominal controller $\tilde{K}$ at q_0 as before, and scheduling through $\Phi(q)$, which depend explicitly on q , so that $K^{(1)}(q) = K_0 + \text{feedback}(\tilde{K}, -\Phi(q))$, and (b) computing $\tilde{K}(q)$ which depends on q , and using $K^{(2)}(q) = K_0 + \text{feedback}(\tilde{K}(q), -\Phi(q))$.

While (a) uses (3) based on Apkarian and Noll (2006b,c) and available in SYSTUNE, we show that one can also apply (3) to case (b). We use Fig. 4 to work in the finite-dimensional system $(\tilde{G}(q), \tilde{K}(q))$, where plant and controller now depend on q , which is a parameter-varying design.

For that we have to decide on a parametric form of the controller $\tilde{K}(q)$, which we choose as

$$\begin{aligned}\tilde{K}(q, \mathbf{x}) = & \tilde{K}(q_0) + (q - q_0)\tilde{K}_1(\mathbf{x}) \\ & + (q - q_0)^2\tilde{K}_2(\mathbf{x}),\end{aligned}$$

and where we adopted the simple static form $\tilde{K}_1(\mathbf{x}) = [\mathbf{x}_1 \ \mathbf{x}_2 \ \mathbf{x}_3]$, $\tilde{K}_2 = [\mathbf{x}_4 \ \mathbf{x}_5 \ \mathbf{x}_6]$, featuring a total of 6 tunable parameters. The nominal $\tilde{K}(q_0)$ is obtained via (3) as above. For $q_0 = 3$ this leads to $\tilde{K}(q_0) = [-1.049 \ -1.049 \ -0.05402]$, computed via SYSTUNE.

With the parametric form $\tilde{K}(q, \mathbf{x})$ fixed, we now use again the feedback system $(\tilde{G}(q), \tilde{K}(q))$ in Fig. 4 and design a parametric robust controller using the method of Apkarian et al. (2015a), which is included in the SYSTUNE package and used by default if an uncertain closed-loop is entered. The tuning goals are chosen as constraints on closed-loop poles including minimum decay of 0.7, minimum damping of 0.9, with maximum frequency 2. The controller obtained is (with $q_0 = 3$)

$$\begin{aligned}\tilde{K}(q, \mathbf{x}^*) = & \tilde{K}(q_0) + (q - q_0)\tilde{K}_1(\mathbf{x}^*) \\ & + (q - q_0)^2\tilde{K}_2(\mathbf{x}^*),\end{aligned}$$

with $\tilde{K}_1 = [-0.1102, -0.1102, -0.1053]$, $\tilde{K}_2 = [0.03901, 0.03901, 0.02855]$, and we retrieve the final parameter varying controller for $G(q)$ as

$$K^{(2)}(q) = K_0 + \text{feedback}(\tilde{K}(q, \mathbf{x}^*), -\Phi(q)).$$

Nominal and scheduled controllers are compared in simulation in Figs. 6, 7, and 8, which indicate that $K^{(2)}(q)$ achieves the best performance for frozen-in-time values $q \in [2, 4]$. All controllers

Optimization-Based Control Design Techniques and Tools, Fig. 6 Synthesis at nominal $q_0 = 3$. Simulations of nominal $K = K_0 + \text{feedback}(\tilde{K}, \Phi(3))$ for $q = 2, 3, 4$. Nominal controller is robustly stable over $[q, \bar{q}]$

are easily implementable, since only real-rational elements in combination with delays are used.

The non-smooth program (5) was solved with SYSTUNE in 30 s CPU on a Mac OS X with

Optimization-Based Control Design Techniques and Tools, Fig. 7 Method 1. $\tilde{K}$ obtained for nominal $q = 3$, but scheduled $K(q) = K_0 + \text{feedback}(\tilde{K}, \Phi(q))$. Simulations for $q = 2$ top, $q = 3$ middle, $q = 4$ bottom

Optimization-Based Control Design Techniques and Tools, Fig. 8 Method 2. $\tilde{K}(q) = \tilde{K}_{\text{nom}} + (q - 3)\tilde{K}_1 + (q - 3)^2\tilde{K}_2$ and $K(q) = K_0 + \text{feedback}(\tilde{K}(q), \Phi(q))$. Simulations for $q = 2, 3, 4$

2.66 GHz Intel Core i7 and 8 GB RAM. The reader is referred to the MATLAB Control Toolbox 2018b and higher versions for additional examples. More details on this study can be found in Apkarian and Noll (2019).

Abstract

This entry describes the basic setup of linear robust control and the difficulties typically encountered when designing optimization

algorithms to cope with robust stability and performance specifications.

Keywords

Linear systems · Optimization · Robust control

Linear Robust Control

Robust control allows dealing with uncertainty affecting a dynamical system and its environment. In this section, we assume that we have a mathematical model of the dynamical system without uncertainty (the so-called nominal system) jointly with a mathematical model of the uncertainty. We restrict ourselves to **linear systems**: if the dynamical system we want to control has some nonlinear components (e.g., input saturation), they must be embedded in the uncertainty model. Similarly, we assume that the control system is relatively small scale (low number of states): higher-order dynamics (e.g., highly oscillatory but low energy components) are embedded in the uncertainty model. Finally, for conciseness, we focus exclusively on continuous-time systems, even though most of the techniques described in this section can be transposed readily to discrete-time systems.

Our control system is described by the first-order ordinary differential equation

$$\begin{aligned}\dot{x} &= A(\delta)x + D(\delta)u \\ y &= C(\delta)x\end{aligned}$$

where as usual $x \in \mathbb{R}^n$ denotes the states, $u \in \mathbb{R}^m$ denotes the controlled inputs, and $y \in \mathbb{R}^p$ denotes the measured outputs, all depending on time t , with $\dot{x}$ denoting the time derivative of x . The system is subject to uncertainty, and this is reflected by the dependence of matrices A , B , and C on uncertain parameter δ which is typically time varying and restricted to some bounded set

$$\delta \in \Delta \subset \mathbb{R}^q.$$

A linear control law

$$u = Ky$$

modeled by a matrix $K \in \mathbb{R}^{m \times p}$ must be designed to overcome the effect of the uncertainty while optimizing some performance criterion (e.g., pole placement, disturbance rejection, H_2 or H_∞ norm). Sometimes, a relevant performance criterion is that the control should be stabilizing for the largest possible uncertainty (measured, e.g., by some norm on Δ). In this section, for conciseness, we restrict our attention to **static output feedback** control laws, but most of the results can be extended to dynamical output feedback control laws, where the control signal u is the output of a controller (a linear system to be designed) whose input is y .

Uncertainty Models

Among the simplest possible uncertainty models, we can find the following:

- **Unstructured uncertainty**, also called norm-bounded uncertainty, where

$$\Delta = \{\delta \in \mathbb{R}^q : \|\delta\| \leq 1\}$$

and the given norm can be a standard vector norm or a more complicated matrix norm if δ is interpreted as a vector obtained by stacking the column of a matrix

- **Structured uncertainty**, also called polytopic uncertainty, where

$$\Delta = \text{conv} \{\delta_i, i = 1, \dots, N\}$$

is a polytope modeled as the convex combination of a finite number of given vertices $\delta_i \in \mathbb{R}^q, i = 1, \dots, N$

We can find more complicated uncertainty models (e.g., combinations of the two above: see Zhou et al. 1996), but to keep the developments elementary, they are not discussed here.

Nonconvex Nonsmooth Robust Optimization

The main difficulties faced when seeking a feedback matrix K are as follows:

- **Nonconvexity**: The stability conditions are typically nonconvex in K .
- **Nondifferentiability**: The performance criterion to be optimized is typically a non-differentiable function of K .
- **Robustness**: Stability and performance should be ensured for every possible instance of the uncertainty.

So if we are to formulate the robust control problem as an optimization problem, we should be ready to develop and use techniques from nonconvex, nondifferentiable, robust optimization.

Let us first elaborate on the first difficulty faced by optimization-based robust control, namely, the nonconvexity of the stability conditions. In continuous time, stability of a linear system $\dot{x} = Ax$ is equivalent to negativity of the spectral abscissa, which is defined as the maximum real part of the eigenvalues of A :

$$\alpha(A) = \max\{\text{Re } \lambda : \det(\lambda I_n - A) = 0, \lambda \in \mathbb{C}\}.$$

It turns out that the open cone of matrices $A \in \mathbb{R}^{n \times n}$ such that $\alpha(A) < 0$ is nonconvex (Ackermann 1993). This is illustrated in Fig. 1 where we represent the set of vectors $K = (k_1, k_2, k_3) \in \mathbb{R}^3$ such that $k_1^2 + k_2^2 + k_3^2 < 1$ and $\alpha(A(K)) < 0$ for

$$A(K) = \begin{pmatrix} -1 & k_1 \\ k_2 & k_3 \end{pmatrix}.$$

There exist various approaches to handling nonconvexity. One possibility consists of building convex inner approximations of the stability region in the parameter space. The approximations can be polytopes, balls, ellipsoids, or more complicated convex objects described by linear matrix inequalities (LMI). The resulting stability conditions are convex, but surely conservative, in the sense that the conditions are only sufficient for stability and not necessary. Another approach to handling nonconvexity consists of formulating the stability conditions algebraically (e.g., via the Routh-Hurwitz stability criterion or its symmetric version by Hermite) and using converging hierarchies of LMI relaxations to solve

Optimization-Based Robust Control, Fig. 1 A nonconvex ball of stable matrices

Optimization-Based Robust Control, Fig. 2 The spectral abscissa is typically nonconvex and nonsmooth

the resulting nonconvex polynomial optimization problem: see, e.g., Henrion and Lasserre (2004) and Chesi (2010).

The second difficulty characteristic of optimization-based robust control is the potential nondifferentiability of the objective function. Consider for illustration one of the simplest optimization problems which consists of minimizing

the spectral abscissa $\alpha(A(K))$ of a matrix $A(K)$ depending linearly on a matrix K . Such a minimization makes sense since negativity of the spectral abscissa is equivalent to system stability. Then typically, $\alpha(A(K))$ is a continuous but non-Lipschitz function of K , which means that its gradient can be unbounded locally. In Fig. 2, we plot the spectral abscissa $\alpha(A(K))$ for

Optimization-Based Robust Control, Fig. 3

The graph of the negative spectral abscissa for some randomly generated matrix parametrizations

$$A(K) = \begin{pmatrix} 0 & 1 \\ K & -K \end{pmatrix}$$

and $K \in \mathbb{R}$. The function is non-Lipschitz at $K = 0$, at which the global minimum $\alpha(A(0)) = 0$ is achieved. Nonconvexity of the function is also apparent in this example. The lack of convexity and smoothness of the spectral abscissa and other similar performance criteria renders optimization of such functions particularly difficult (Burke et al. 2001, 2006b). In Fig. 3, we represent graphs of the spectral abscissa (with flipped vertical axis for better visualization) of some small-size matrices depending on two real parameters, with randomly generated parametrization. We observe the typical nonconvexity and lack of smoothness around local and global optima.

The third difficulty for optimization-based robust control is the uncertainty. As explained above, optimization of a performance criterion with respect to controller parameters is already a potentially difficult problem for a nominal system (i.e., when the uncertainty parameter is equal to zero). This becomes even more difficult when this optimization must be carried out for

all possible instances of the uncertainty δ in Δ . This is where the above assumption that the uncertainty set Δ has a simple description proves useful. If the uncertainty δ is unstructured and not time varying, then it can be handled with the complex stability radius (Ackermann 1993), the pseudospectral abscissa (Trefethen and Embree 2005), or via an H_∞ norm constraint (Zhou et al. 1996). If the uncertainty δ is structured, then we can try to optimize a performance criterion at every vertex in the polytopic description (which is a relaxation of the problem of stabilizing the whole polytope). An example is the problem of simultaneous stabilization, where a controller K must be found such that the maximum spectral abscissa of several matrices $A_i(K)$, $i = 1, \dots, N$ is negative (Blondel 1994). Finally, if the uncertainty δ is time varying, then performance and stability guarantees can still be achieved with the help of Lyapunov certificates or potentially conservative convex LMI conditions: see, e.g., Boyd et al. (1994) and Scherer et al. (1997).

A unified approach to addressing conflicting performance criteria and uncertainty consists of searching for locally optimal solutions of a nonsmooth optimization problem that is built

to incorporate minimization objectives and constraints for multiple plants. This is called (linear robust) **multiobjective control**, and formally, it can be expressed as the following optimization problem

$$\begin{aligned} \min_K \max_{i=1,\dots,N} \{g_i(K) : \beta_i = \infty\} \\ \text{s.t. } g_i(K) \leq \beta_i, i = 1, \dots, N, \end{aligned}$$

where each $g_i(K)$ is a function of the closed-loop matrix $A_i(K)$ (e.g., a spectral abscissa or an H_∞ norm) and the scalars β_i are given and such that if $\beta_i = \infty$ for some i , then g_i appears in the objective function and not in a constraint: see Gumussoy et al. (2009) for details. In the above problem, the objective function, a maximum of nonsmooth and nonconvex functions, is typically also nonsmooth and nonconvex. Moreover, without loss of generality, we can easily impose a sparsity pattern on controller matrix K to account for structural constraints (e.g., a low-order decentralized controller).

Software Packages

Algorithms for **nonconvex nonsmooth optimization** have been developed and interfaced for linear robust multiobjective control in the public domain Matlab package HIFOO released in 2006 (Burke et al. 2006a) and updated in 2009 (Gumussoy et al. 2009) and based on the theory described in Burke et al. (2006b). In 2011, The MathWorks released HINFSTRUCT, a commercial implementation of these techniques based on the theory described in Apkarian and Noll (2006).

Option Games: The Interface Between Optimal Stopping and Game Theory

Benoît Chevalier-Roignant¹ and Lenos Trigeorgis²

Abstract

Managers can stake a claim by committing to capital investments today that can influence their rivals' behavior or take a "wait-and-see" or step-by-step approach to avoid possible adverse market consequences tomorrow. At the core of this corporate dilemma lies the classic trade-off between commitment and

flexibility. This trade-off calls for a careful balancing of the merits of flexibility against those of commitment. This balancing is captured by option games.

Keywords

Real options · Game theory · Option games · Optimal stopping

Introduction

The global competitive environment has become increasingly challenging as modern economies undergo unprecedented changes in the midst of the global economic turmoil. Real-world dilemmas corporate managers face today are driven by the interplay among strategic and market uncertainty. The tech industry has evolved most rapidly, putting companies unable to respond to market developments and technological breakthroughs at severe disadvantage. Corporate management's plans and how they implement their strategy will likely determine whether the firm will survive and be successful in the marketplace or become extinct.

Formulating the right strategy in the right competitive environment at the right time is a nontrivial task. Whether to invest in a new technology or a new product or enter a new market is a strategic decision of immense importance. Corporate management must assess strategic options with proper analytical tools that can help determine whether to commit to a particular strategic path, given scarce or costly resources, or whether to stay flexible. Oftentimes, firms need to position themselves flexibly to capitalize on future opportunities as they emerge while limiting potential losses arising from adverse future circumstances. In many cases, corporate managers find themselves in need to revise their decision plans in view of actual market developments when facing an uncertain future; they can then decide to undertake only those projects with sufficiently high prospects in the future to justify commitment at that time. This needs to be balanced with the need to make irreversible strategic commitments to seize first-mover advantage presenting

rivals with a fait accompli to which they have no choice but adapt.

Capital Budgeting Ignoring Strategic Interactions

Net Present Value

Prevailing management approaches simplify matters and often lead to investment decisions that are detrimental to the firm's long-term well-being. Suppose a firm's future cash flow at time t is given by a random variable X_t . Cash flows then evolve as a geometric Brownian motion

$$dX_t = gX_t dt + \sigma X_t dB_t \quad \text{and } X_0 = x,$$

with drift parameter g and volatility σ . The Brownian motion $(B_t; t > 0)$ captures exogenous market uncertainty. The standard criterion used in corporate finance is based on discounted cash flows (DCF) or net present value (NPV). This consists in assessing the current value of a project by discounting the expected future cash flows $\mathbb{E}[X_t]$ at a constant discount rate, $r (> g)$. Management supposedly creates shareholder value by undertaking projects with positive NPV, i.e., projects for which the present value of cash flows, $v(x) := \int_0^\infty e^{-rt} \mathbb{E}[X_t] dt$, exceeds the necessary investment cost, I . In the present case, the firm will invest under the zero-NPV criterion if

$$\frac{x}{r - g} \geq I. \quad (1)$$

This traditional criterion views investment opportunities as now-or-never decisions under passive management. However, this precludes the possibility to adjust future decisions in case the market develops off the expected path. While market uncertainty is factored in through the discount rate, the flexibility management has is typically not properly accounted for.

Real Options Analysis

It has become standard practice in finance and strategy to interpret real investment opportunities as being analogous to financial options. This view

is well accepted among academics and practitioners alike and is at the core of real options analysis (ROA). ROA is an extension of option-pricing theory to real investment situations (Myers 1977; Trigeorgis 1996). This approach effectively allows one to capture the dynamic nature of decision-making since it factors in management's flexibility to revise and adapt its decision in the face of market uncertainty. ROA allows managers with flexibility to adapt to actual market developments as uncertainty gets resolved. Managers may, for example, delay the start (or closure) of a project depending on its prospects. This approach leverages on optimal stopping theory (see, e.g., Bensoussan and Lions 1982; Dixit and Pindyck 1994) and is considered to be more reflective of real decision-making than traditional methods. In the case the firm can delay the decision to invest, for example, the problem is one of optimal stopping:

$$V(s) := \sup_{\tau} \mathbb{E} e^{-r\tau} [v(X_{\tau}) - I].$$

The discount rate is the risk-free interest rate (Dixit and Pindyck 1994; Trigeorgis 1996). The time of managerial action, τ , is now a decision variable – random as the decision-maker faces an uncertain environment. This problem has an analytical solution characterized by a threshold policy, say a trigger $\bar{x}$, given by

$$\frac{\bar{x}}{r - g} = \frac{\beta}{\beta - 1} I \quad (2)$$

where β is the positive root of a quadratic function (see, e.g., Dixit and Pindyck 1994) and $\beta/(\beta - 1) > 1$. When decisions are costly or difficult to reverse, corporate managers would be more cautious and careful to make decisions. A firm should not always commit immediately – even if the NPV criterion (1) indicates so – but wait until the gross project value is sufficiently positive to cover the investment cost I by a factor larger than one, as expressed in (2). Investing prematurely may destroy shareholder value. Real options may justify sometimes undertaking projects with negative (static) net present value

if it creates a platform for growth options or delaying projects with positive NPV.

Accounting for Strategic Interactions in Capital Budgeting

Strategic Uncertainty

As natural monopolies have lost their secular well-protected positions owing to market liberalization in the European Union and elsewhere across the globe, strategic interdependencies have become new key challenge for managers. At the same time, sectors traditionally populated by multiple firms have undergone significant consolidation, often resulting in oligopolistic situations with a reduced number of players (e.g., Facebook in social media, Google in search, Amazon in e-commerce). The 2008 economic crisis has amplified these consolidation pressures. These two ongoing phenomena – liberalization and consolidation – have put high on the corporate agenda the assessment of strategic options under competition. Standard real options analysis often examines investment decisions as if the option holder has a proprietary right to exercise. This perspective may not be realistic in the new oligopolistic environment as several firms may share the right to a related investment opportunity in the industry.

Game Theory

In oligopolistic industries, firms often have difficulty predicting how rivals will behave and make decisions based on beliefs about their likely behavior. A theory that helps characterize beliefs and form predictions about which strategies opponents will follow is helpful in analyzing such oligopolistic situations. Game theory has traditionally been used to frame strategic interactions arising in conflict situations involving parties with different objectives or interests. In competitive markets, firms' actions have no material impact on the market outcomes and conversely on their rivals' decisions. Consequently, competitive equilibria can be derived without the use of game theoretical techniques. Game theory attempts to model behavior in

strategic situations or games in which one party's success based on its choices depends on the choices of other players through influencing one another's welfare. Game theory adopts a different perspective on optimization, as the focus is on the formation of beliefs about rivals' optimal strategies. Finance theory has been primarily concerned with "moves by nature," while game theory focuses on "optimization problems" involving multiple players. To solve a game, one needs to reduce a complex multiplayer problem into a simpler structure that captures the essence of the conflict situation. One can then derive useful predictions about how rivals are likely to react in a given situation. Game theory helped reshape microeconomics by providing analytical foundations for the study of market behavior and has been at the foundation of the Nobel Prize winning research field of industrial organization.

Dynamic game theory (see, e.g., Başar and Olsder 1998) addresses problems in which several parties are in repeated interaction. Strategic management approaches based on dynamic economic theory can provide a richer foundation for understanding developments and competitive reactions within an industry. As firm competitiveness involves interactions among several players (rivals, Suppliers, or clients), game theoretic analysis brings important insights into strategic management in addressing such issues as first- and second-mover advantages, firm entry and exit decisions, strategic commitment, reputation, signaling, and other informational effects. A key lesson is that, when firms react to one another, it may sometimes be appropriate for one firm to take an aggressive stance in expectation that rivals will back off. Dynamic industrial organization includes the analysis of "games of timing" such as preemption games or war of attrition, whereby firms decide on appropriate investment timing under rivalry.

Option Games

The earlier optimal stopping problem with several firms falls in the category of "games of timing" when a firm's entry decision influences another firm's market strategy. Option games are most suitable to help model situations where a firm that has a real option to (dis)invest faces

rivalry. When two (or more) firms decide on entry or more generally compete over a first-mover advantage, they face a "preemption game," while, if they decide on market exit or more generally wait to benefit from a "second-mover advantage," they face a "war of attrition."

In preemption games under uncertainty, the mathematical problem consists in finding a Nash equilibrium solution for the two-player equivalent of the above optimal stopping problem. This solution must also satisfy certain dynamic consistency criteria. For sequential investments, the follower is faced with a single-agent optimal investment timing problem; it will thus enter if the gross project value exceeds the investment cost by a sufficient factor. A firm entering the market early on, i.e., a leader, earns temporary monopoly rents as long as demand remains below the follower's entry threshold. Following the follower's entry, the firms act as a duopoly. A key question is whether the roles of the firms (i.e., leader vs. follower) are set or if they are part of an equilibrium. The case where the roles are set have been studied among others by Bensoussan et al. (2010). It is, however, more common to assume the roles are endogenous (see, e.g., Smets 1991; Grenadier 1996; Thijssen et al. 2012; Riedel and Steg 2017) as discussed below.

As long as the leader's value exceeds the follower's, there is an incentive for one firm to invest, but not necessarily for both of them, leading to a "coordination problem." The competitive pressure will dissipate away the leader's first-mover advantage, leading to a market entry point that is not socially optimal and to rent dissipation. Unfortunately, the multiplayer problem does not involve a simple analytical solution, since at each point a duopolist firm might end up in any of four distinct situations (two-by-two matrix) depending on the rival's entry decision. Option games indicate in each situation which driving force (commitment vs. flexibility) prevails and whether to go ahead with the investment or wait and see. Main drivers of the prevailing market equilibrium include the riskiness of the venture, σ , the magnitude of the first-mover advantage, and the exclusive or shared ability to reap the benefits of the investment vis-à-vis rivals. When firms can grasp a large first-mover advantage from investing early

but cannot differentiate themselves sufficiently from each other, they may be tempted to wage a preemptive war, investing prematurely at an early market stage that actually kills option value. If firms are more on an equal footing but do not see much benefit from investing early, they may prefer to wait and invest (jointly) at a later stage when the future market is sufficiently mature. If, however, one firm has a comparative cost advantage (e.g., a radical or drastic technological superiority), participants may prefer a consensual leader-follower investment arrangement involving less option value destruction.

ROA has traditionally focused on modeling timing decisions. Increasingly, academics account for richer strategy (see, e.g., Bensoussan and Chevalier-Roignant 2019). Following Huisman and Kort (2015), several papers discuss cases in which the two competing firms decide on their investment lump sums beside their investment times (see review in Huberts et al. 2015). Beside competitors, other stakeholders may be affected by a firm's decision. We should expect a greater convergence between the literature on real options and on principal-agent problems in continuous time (Sannikov 2008; Cvitanic and Zhang 2012).

Summary and Future Directions

Corporate management's strategic tool kit should provide clearer guidance on whether to pursue a wait-and-see stance in the face of uncertain market developments or jump on the first-mover bandwagon to build competitive advantage. We discussed two different modeling approaches that provide complementary perspectives and insights to help management deal with issues of flexibility versus commitment: real options and dynamic game theory. While each approach separately might turn a blind eye to flexibility or commitment, an integrative perspective through "options games" might provide the right balance and serve as a tool kit for adaptive competitive strategy. Both perspectives ultimately aim to derive better insights into industry dynamics under industry conditions characterized by both market and strategic uncertainty. Option games pave the way

for a consistent approach in addressing managerial decision-making, elevating the art of strategy to scientific analysis. Option games integrate in a common, consistent framework recent advances made in these diverse set of disciplines. This emerging field represents a promising strategic management tool that can help guide managerial decisions through the complexity of the modern competitive marketplace.

Oscillator Synchronization

Bruce A. Francis

Department of Electrical and Computer Engineering, University of Toronto, Toronto, ON, Canada

Abstract

The nonlinear Kuramoto equations for n coupled oscillators are derived and studied. The oscillators are defined to be synchronized when they oscillate at the same frequency and their phases are all equal. A control-

theoretic viewpoint reveals that synchronized states of Kuramoto oscillators are locally asymptotically stable if every oscillator is coupled to all others. The problem of synchronization in Kuramoto oscillators is closely related to rendezvous, consensus, and flocking problems in distributed control. These problems, with their elegant solution by graph theory, are discussed briefly.

Keywords

Graph theory · Kuramoto model · Laplacian · Oscillator · Synchronization

Introduction

An oscillator is an electronic circuit or other kind of dynamical system that produces a periodic signal. If several oscillators are coupled together in some fashion and the periodic signals that they each produce are of the same frequency and are in phase, the oscillators are said to be synchronized. The book *Sync: The Emerging Science of Spontaneous Order*, by Strogatz, introduces a wide variety of phenomena where oscillators synchronize. Some examples from biology: networks of pacemaker cells in the heart, circadian pacemaker cells in the suprachiasmatic nucleus of the brain, metabolic synchrony in yeast cell suspensions, groups of synchronously flashing fireflies, and crickets that chirp in unison. Engineering examples include clock synchronization in distributed communication networks and electric power networks with synchronous generators.

A very simple example of oscillator synchronization was discovered by Christiaan Huygens, the prominent Dutch scientist and mathematician who lived in the 1600s. One of his contributions was the invention of the pendulum clock, where a pendulum swings back and forth with a constant frequency. Huygens observed that two pendulum clocks in his house synchronized after some time. The explanation for this phenomenon is that the pendula were coupled mechanically through the wooden frame of the house. The same principle can be observed by a fun, simple experiment. As

Oscillator Synchronization, Fig. 1 Two metronomes on a board that is on two pop cans. After the metronomes are let go at the same frequency but at different times, they soon become synchronized and tick in unison.

in Fig. 1, put two pop cans on a table, on their sides and parallel to each other. Place a board on top of them, and place two (or more) metronomes on the board. Set the metronomes to tick at the same frequency. Start them off ticking but not in unison. Within a few minutes they will be ticking in unison.

In this essay we derive what are known as the Kuramoto equations, a mathematical model of n oscillators, and then we study when they will synchronize.

The Kuramoto Model

In 1975 the Japanese researcher Yoshiki Kuramoto gave one of the first serious mathematical studies of coupled oscillators. To derive Kuramoto's equations, we begin with a simple hypothetical setup. Imagine n runners going around a circular track. Suppose they're all going at roughly the same speed, but each adjusts his/her speed based on the speeds of his/her nearest neighbors. If some runner passes another, that one tends to speed up to close the gap. The synchronization question is do the runners eventually end up running together in a tight pack?

Idealize the runners to be merely points, numbered $k = 1, \dots, n$. They move on the unit circle in the complex plane. A point on the unit circle can be written as $e^{j\theta}$, where j denotes the unit imaginary number and θ denotes the angle measured counterclockwise from the positive real axis. The position of point k at time t is

Oscillator Synchronization, Fig. 2 Left: The vectors p_k and jp_k . Right: The local velocity v_k

$z_k(t) = e^{j(\omega t + \theta_k(t))}$, where ω is the nominal rotational speed in rad/s, and $\theta_k(t)$ is the difference between the actual angle at time t and the nominal angle ωt . Notice that ω is a constant positive real number and it is the same for all n points. As in circuit theory, it simplifies the mathematics to refer all the positions to the sinusoid $e^{j\omega t}$, and therefore we define the **local position** of point k to be $p_k(t) = z_k(t)/e^{j\omega t}$, i.e., $p_k(t) = e^{j\theta_k(t)}$. Differentiate the local position with respect to time and let “dot” denote d/dt : $\dot{p}_k = e^{j\theta_k} j\dot{\theta}_k$. Define the local rotational velocity $v_k = \dot{\theta}_k$ and substitute into the preceding equation:

$$\dot{p}_k = v_k j p_k. \quad (1)$$

The local velocity v_k could be positive or negative. Notice that if we view p_k as a vector from the origin and view multiplication by j as rotation by $\pi/2$, then jp_k can be viewed as tangent to the circle at the point p_k – see the picture on the left in Fig. 2.

Now we propose a feedback law for v_k in Eq. (1); see the picture on the right in Fig. 2. Take v_k proportional to the projection of p_i onto the tangent at p_k , that is, $v_k = \langle p_i, jp_k \rangle$. Here the inner product between two complex numbers v, w is $\langle v, w \rangle = \text{Re } \bar{v}w$. (You may check that this is equivalent to the usual dot product of vectors in $\mathbb{R}^2$.) Thus from (1) the model to get k to close the gap is $\dot{p}_k = \langle p_i, jp_k \rangle jp_k$.

More generally, suppose that point k pays attention to not just point i but a fixed set of points called its **neighbors**. Let $\mathcal{N}_k$ denote the index set of neighbors of point k and for simplicity assume $\mathcal{N}_k$ does not depend on time. We consider the

control law $v_k = \sum_{i \in \mathcal{N}_k} \langle p_i, j p_k \rangle$ and thereby arrive at the model of the evolution of the positions p_k :

$$\dot{p}_k = \sum_{i \in \mathcal{N}_k} \langle p_i, j p_k \rangle j p_k.$$

However, the Kuramoto model gives the evolution of the angles θ_k rather than the points p_k . To find the equation for θ_k , we observe that

$$\begin{aligned} \langle p_i, j p_k \rangle &= \operatorname{Re}(\bar{p}_i j p_k) \\ &= \operatorname{Re}\left(e^{-j\theta_i} j e^{j\theta_k}\right) \\ &= \sin(\theta_i - \theta_k). \end{aligned}$$

In this way, the controlled points move according to

$$\dot{p}_k = \sum_{i \in \mathcal{N}_k} \sin(\theta_i - \theta_k) j p_k.$$

Substitute in $p_k = e^{j\theta_k}$ and then cancel $j p_k$:

$$\dot{\theta}_k = \sum_{i \in \mathcal{N}_k} \sin(\theta_i - \theta_k), \quad k = 1, \dots, n. \quad (2)$$

This is the **Kuramoto model of coupled oscillators** in terms of the phases of the oscillators. There are n coupled nonlinear ordinary differential equations.

Equation (2) has the vector form $\dot{\theta} = g(\theta)$. There are some variations in the literature about the state space associated with this equation. It is important to get the state space right because otherwise the concepts of stability and synchronization become shaky. The phase angles θ_k are real numbers with units of radians, so at first glance the state space is $\mathbb{R}^n$. But the angles are defined modulo 2π and so their values are restricted to lie in the interval $[0, 2\pi)$. In this way the state space becomes $[0, 2\pi)^n$. For example, if $n = 2$ the state space is the square $[0, 2\pi) \times [0, 2\pi)$ viewed as a subset of the plane $\mathbb{R}^2$. The mapping $\phi \mapsto e^{j\phi}$ is a one-to-one correspondence from the interval $[0, 2\pi)$ to the unit circle in the complex plane $\mathbb{C}$. This unit circle is usually denoted $\mathbb{S}^1$, the superscript signifying the circle's dimension as a manifold. By this correspondence the state space

of (2) is the n -fold product $\mathbb{S}^1 \times \dots \times \mathbb{S}^1$, and this is sometimes called the n -torus, denoted $\mathbb{T}^n$.

To recap, in what follows, the state space is $[0, 2\pi)^n$. This is an n -dimensional manifold rather than a vector space.

Synchronization

Control-theoretic methods, for example, that of Sepulchre et al. (2007), have been insightful. We address now the question of whether or not the oscillators in (2) synchronize, that is, the phases asymptotically converge to a common value. In the state space, $[0, 2\pi)^n$, the set of synchronized states is the set of vectors θ of the form $c\mathbf{1}$, where $c \in [0, 2\pi)$ and $\mathbf{1}$ is the vector of 1's. The simplest case is when every point is a neighbor of every other point, i.e., $\mathcal{N}_k$ contains every integer in the set $1, \dots, n$ except k . Then (2) becomes

$$\dot{\theta}_k = \sum_{i=1}^n \sin(\theta_i - \theta_k), \quad k = 1, \dots, n. \quad (3)$$

Let us show that if the initial phases $\theta_k(0)$ are all close enough together, then $\theta(t)$ converges asymptotically to a synchronized state. This will show that the synchronized states are locally asymptotically stable in a certain sense.

As stated before, Eq. (3) has the form $\dot{\theta} = g(\theta)$. The function $g(\theta)$ is the gradient of a positive definite function. Indeed, let $r e^{j\psi}$ denote the average of the points $e^{j\theta_1}, \dots, e^{j\theta_n}$. Of course, r and ψ are functions of θ , and so we have

$$r(\theta) e^{j\psi(\theta)} = \frac{1}{n} \left(e^{j\theta_1} + \dots + e^{j\theta_n} \right)$$

and therefore

$$r(\theta) = \frac{1}{n} \left| e^{j\theta_1} + \dots + e^{j\theta_n} \right|.$$

The average of n points on the unit circle lives inside the unit disc, and therefore $r(\theta)$ is a real number between 0 and 1. It equals 1 if and only if the n points are equal, that is, the n phases are

equal, and this is the state where the phases are synchronized.

Define the function

$$\begin{aligned} V(\theta) &= \frac{n^2}{2} r(\theta)^2 \\ &= \frac{1}{2} \left| e^{j\theta_1} + \dots + e^{j\theta_n} \right|^2 \\ &= \frac{1}{2} \left(e^{j\theta_1} + \dots + e^{j\theta_n} \right) \left(e^{-j\theta_1} + \dots + e^{-j\theta_n} \right). \end{aligned}$$

Thus

$$\frac{\partial V(\theta)}{\partial \theta_k} = \sin(\theta_1 - \theta_k) + \dots + \sin(\theta_n - \theta_k)$$

and therefore (3) can be written as $\dot{\theta} = \partial V(\theta)/\partial \theta$. This is a gradient equation. If $\theta(0)$ is chosen so that all the phases are close enough together, then $r(\theta(0))$ will be close to 1, and therefore θ will move in a direction to increase $V(\theta)$, that is, increase $r(\theta)$, until in the limit $r(\theta) = 1$ and the phases are synchronized.

There are results, e.g., Sepulchre et al. (2008), when the coupling is not all-to-all. Also, the term “synchronization” is used more generally than just for oscillators Wieland et al. (2011).

Rendezvous, Consensus, Flocking, and Infinitely Many Oscillators

Synchronization of coupled oscillators is closely related to other problems known as rendezvous, consensus, or flocking problems. Phase synchronization is replaced by the requirement of mobile robots gathering at some location, by the requirement of temperature sensors in a sensor network converging to the same temperature estimate, or by the requirement that mobile robots should head in the same direction. The simplest form of these problems has the equations

$$\dot{\theta}_k = \sum_{i \in \mathcal{N}_k} (\theta_i - \theta_k), \quad k = 1, \dots, n. \quad (4)$$

Notice that this can be obtained from the Kuramoto model (2) merely by replacing $\sin(\theta_i - \theta_k)$ by $\theta_i - \theta_k$ in (2), that is, by

linearizing the latter at a synchronized state. We shall continue to call θ_k a phase of an oscillator. When do the phases evolving according to (4) synchronize? The answer to the question involves a lovely collaboration between graph theory and dynamics.

Introduce a directed graph that is in one-to-one correspondence with the neighbor structure. The graph is made up of n nodes, one for each oscillator. From each node there is an arrow to every neighbor of that node; that is, from node k is an arrow to every node in $\mathcal{N}_k$. Denote the adjacency matrix and the degree matrix of the graph by, respectively, A and D . That is, $a_{ij} = 1$ if j is a neighbor of i and d_{ii} equals the sum of the elements on row i of A . The **Laplacian** of the graph is defined to be $L = D - A$. Then (4) is equivalent to simply

$$\dot{\theta} = -L\theta, \quad (5)$$

where θ is still the vector with elements $\theta_1, \dots, \theta_n$. Whether or not synchronization occurs depends on the connectivity of the graph. We stop here and refer the reader to the articles [► Averaging Algorithms and Consensus](#) and [► Flocking in Networked Systems](#)

Suppose there are an infinite but countable number of oscillators in the model (5). When will they synchronize? To answer this, we have to be more specific.

Let us allow an infinite number of oscillators numbered by the integers, positive, zero, and negative. Denote the phases by θ_k and let θ denote the phase vector, whose k th component is θ_k . Assume each oscillator has only finitely many neighbors, let $\mathcal{N}_k$ denote the set of neighbors of oscillator k , and let L be the Laplacian of the associated graph. Finally, let $\theta(t)$ evolve according to the Eq. (5). This equation isn't automatically well posed in the sense that there may not be a solution defined for all $t > 0$. We have to impose a framework so that solutions do indeed exist. One natural space in which to place $\theta(0)$ is ℓ^2 , the Hilbert space of square-summable sequences. If L is a bounded operator on ℓ^2 , then so is e^{-Lt} for every $t > 0$, and hence the phase vector exists and belongs to ℓ^2 for every $t > 0$. Another

natural space in which to place $\theta(0)$ is ℓ^∞ , the Banach space of bounded sequences. Again, a phase vector exists for all $t > 0$ if L is a bounded operator on ℓ^∞ .

The following example is from Feintuch and Francis (2012). Take the neighbor sets to be $\mathcal{N}_k = \{k - 1\}$. The graph is a chain: There is an arrow from node k to node $k - 1$, for every k , and the Laplacian is the infinite matrix with 1 on the diagonal, -1 on the first subdiagonal, and zero elsewhere. This Laplacian is a bounded operator on both ℓ^2 and ℓ^∞ . Now the vector $c\mathbf{1}$, where $\mathbf{1}$ is the vector of all 1's, belongs to ℓ^∞ for every real number c , but it belongs to ℓ^2 only for $c = 0$. So the phases can potentially synchronize at any value in ℓ^∞ , but only at 0 in ℓ^2 . For the example under discussion, if the initial phase vector is in ℓ^2 , then the phases synchronize at 0. By contrast, there exist initial phase vectors in ℓ^∞ such that synchronization does not occur. Even worse, $\lim_{t \rightarrow \infty} \theta(t)$ does not exist. The conclusion is that whether or not the oscillators will synchronize is a difficult question in general.

Summary and Future Directions

The Kuramoto model is a widely used paradigm for coupled oscillators. The model has the form $\dot{\theta} = f(E\theta)$, where θ is the vector of phases, the matrix E maps θ into the vector of possible differences $\theta_i - \theta_k$, and f is a function. The Kuramoto model considered in this essay is not the most general. A more general model allows different frequencies ω_k instead of just one, and also a coupling gain K , leading to the model

$$\dot{\theta}_k = \omega_k + \frac{K}{n} \sum_{i \in \mathcal{N}_k} \sin(\theta_i - \theta_k), \quad k = 1, \dots, n. \quad (6)$$

An important problem associated with the Kuramoto model is to determine which synchronized states are stable. The linearized equation is interesting in its own right and relates to problems of rendezvous, consensus, and flocking.

Reference Dörfler and Bullo (2014) offers some questions for future study. In particular, it would be interesting to extend the Kuramoto model beyond the first-order oscillators of (2). Also, the case of general neighbor sets has much room for exploration.

Asymptotic stability is a robust property. For example, if the origin is asymptotically stable for the system $\dot{x} = Ax$, it remains so if A is perturbed by a sufficiently small amount. This is because the spectrum of a matrix is a continuous function of the matrix. The sketch in Fig. 1 vividly depicts the concept of synchronized oscillators. A topic for future study is that of robustness. Mathematically, if the two metronomes are identical, they will synchronize perfectly – this can be proved. Of course, physically two metronomes cannot be identical, and yet they will synchronize if they are close enough physically. A mathematical study of this phenomenon might be interesting.

Recommended Reading

The literature on the Kuramoto model is huge – there are now many hundreds of journal papers continuing the study of oscillators using Kuramoto's model. There is space here only to highlight a few sources.

You can find a mathematical study of coupled metronomes in Pantaleone (2002). Also, Pantaleone's webpage [Pantaleone](#) describes some experimental observations. Kuramoto's original paper is Kuramoto (1975). Dörfler and Bullo have recently written a comprehensive survey (Dörfler and Bullo (2014)). Strogatz has written extensively on oscillator synchronization. His book *Sync* is fascinating and is highly recommended (Strogatz 2004). See also Strogatz

(2000) and Strogatz and Stewart (1993). The papers Scardovi et al. (2007) and Dörfler and Bullo (2011) are recommended for more recent results, the latter treating the general model (6).

Getting phases in oscillators to synchronize is a special case of getting the states or outputs of coupled systems asymptotically to converge to a common value. There is a very large number of references on these subjects, a seminal one being Jadbabaie et al. (2003); others are Lin et al. (2007) and Moreau (2005). Regarding infinitely many oscillators, the physics literature treats only a continuum of oscillators, whereas countably many oscillators are the subject of Feintuch and Francis (2012).

Acknowledgments I greatly appreciate the help from Luca Scardovi, Florian Dörfler, and Francesco Bullo.

Output Regulation Problems in Hybrid Systems

Sergio Galeani

Dipartimento di Ingegneria Civile e Ingegneria Informatica, Università di Roma “Tor Vergata”, Roma, Italy

Abstract

This entry discusses some of the salient features of the output regulation problem for hybrid systems, especially in connection with the steady-state characterization. In order to better highlight such peculiarities, the discussion is mostly focused on the simplest class of linear time-invariant systems exhibiting such behaviors. In comparison with the usual regulation theory, the role played by the zero dynamics and by the presence of more inputs than outputs is particularly striking.

Keywords

Disturbance rejection · Hybrid systems · Internal model principle · Output regulation · Tracking · Zero dynamics

Introduction

Output regulation is one of the most classical problems in control theory, and its celebrated solution in the linear time-invariant case (Davison

1976; Francis and Wonham 1976) is characterized by remarkable elegance and ideas (like the internal model principle). While the extension to nonlinear systems is still an active field of investigation, the study of output regulation for hybrid systems is also being actively pursued, and several surprising results have already appeared for the linear case, suggesting that a richer structure arises in hybrid output regulation problems due to the interplay between flow and jump dynamics.

The problem can be stated as follows. A known *exosystem* $\mathcal{E}$ with initial state belonging to a suitably defined set $\mathcal{W}_0$ produces a signal w possibly affecting both the *plant* $\mathcal{P}$ and the *compensator* $\mathcal{C}$; the compensator has to guarantee that for any initial state of $\mathcal{E}$ in $\mathcal{W}_0$:

- all closed-loop responses are bounded;
- the output e of $\mathcal{P}$ asymptotically converges to zero.

In order to avoid trivialities, the *exosystem* $\mathcal{E}$ is assumed to be such that its state evolution from nonzero initial states in $\mathcal{W}_0$ is bounded and not asymptotically converging to zero, both in forward and in backward time.

Two typical embodiments of the output regulation problem are the *disturbance rejection* and the *reference tracking* problems. In *disturbance rejection*, w acts as a disturbance on $\mathcal{P}$ and cannot be measured by $\mathcal{C}$, and the output e from which the effect of w has to be canceled is the actual plant output. In *reference tracking*, w contains the references to be tracked by an output y_r of $\mathcal{P}$, so that w can be assumed to be known by $\mathcal{C}$; by defining the regulated output e as $e = y_r - r$, the reference tracking problem is cast as an output regulation problem.

The solution of an output regulation problem entails the solution of two subproblems: the definition of a set of *zero output steady-state solutions* and the *asymptotic stabilization* of such solutions (or at least making them *attractive*; in many cases of interest, the achievement of this last objective actually yields asymptotic stabilization). As a matter of fact, the stabilization subproblem is already widely studied and

Output Regulation Problems in Hybrid Systems, Fig. 1 Hybrid time domain $\mathcal{T}$ for a “sampled data” hybrid system. Dots indicate $(t, k) \in \mathcal{T}$ when jumps occur (see section “Hybrid Steady-State Generation” for the t_k notation)

described per se; for this reason, after some short remarks in section “Stabilization Obstructions in Hybrid Regulation,” the remainder of this presentation will focus only on steady-state-related issues, for the simplest class of systems which exhibit the most peculiar and interesting phenomena of hybrid steady-state behavior (see in particular section “Key Features in Hybrid vs Classical Output Regulation”). For concreteness, only hybrid systems $\mathcal{E}, \mathcal{P}$ characterized by linear time-invariant (flow and jump) dynamics will be considered; following Goebel et al. (2012b, Chap. 2), a two-dimensional parameterization of hybrid time $(t, k) \in \mathbb{R} \times \mathbb{N}$ will be used, with t measuring the flow of (usual) time and k counting the number of jumps experienced by the solution (see Fig. 1 for a specific example). So, the exosystem $\mathcal{E}$ will be described at time (t, k) by

$$\dot{w} = Sw, \quad (w, t, k) \in \mathcal{C}_{\mathcal{E}}, \quad (1a)$$

$$w^+ = Jw, \quad (w, t, k) \in \mathcal{D}_{\mathcal{E}}, \quad (1b)$$

and the plant $\mathcal{P}$ will be described at time (t, k) by

$$\dot{x} = Ax + Bu + Pw, \quad (x, u, t, k) \in \mathcal{C}_{\mathcal{P}}, \quad (2a)$$

$$x^+ = Ex + Rw, \quad (x, u, t, k) \in \mathcal{D}_{\mathcal{P}}, \quad (2b)$$

$$e = Cx + Qw, \quad (2c)$$

with $x(t, k) \in \mathbb{R}^n$, $u(t, k) \in \mathbb{R}^m$, $e(t, k) \in \mathbb{R}^p$, $w(t, k) \in \mathbb{R}^q$, and suitably defined flow sets $\mathcal{C}_{\mathcal{E}}$, $\mathcal{C}_{\mathcal{P}}$ and jump sets $\mathcal{D}_{\mathcal{E}}$, $\mathcal{D}_{\mathcal{P}}$.

Stabilization Obstructions in Hybrid Regulation

The achievement of asymptotic stabilization of the desired (zero output) steady-state responses for the considered class of linear hybrid systems crucially depends on whether the plant $\mathcal{P}$ and the exosystem $\mathcal{E}$ have synchronous jump times or not. While assuming synchronous jumps may appear restrictive, it is easy to see that *jumps are always synchronous steady state*, and then the findings (especially necessary conditions) about the synchronous case are fundamental for understanding the asynchronous case.

Asynchronous Jumps

Typically, jumps in $\mathcal{P}$ and $\mathcal{E}$ will be asynchronous, and this will cause the undesirable phenomenon that genuinely close trajectories will look “distant” around each jump when the distance is measured according to the usual Euclidean norm. The simplest illustration of such phenomenon consists in considering two trajectories of the same system starting from ε -close initial conditions. Consider the system

$$\dot{v} = 1, \quad v \in [0, 1], \quad v^+ = 0, \quad v \notin (0, 1),$$

with the initial states $v_0 = 0$ and $v_1 = \varepsilon$, $0 < \varepsilon < 1$. The two ensuing solutions at time (t, k) are immediately computed as

$$v(t, k; v_0) = t - k, \quad t \in [k, k + 1],$$

$$v(t, k; v_1) = \begin{cases} t - k + \varepsilon, & t \in [k, k + 1 - \varepsilon], \\ t - k + \varepsilon - 1, & t \in [k + 1 - \varepsilon, k + 1], \end{cases}$$

Hence, the (Euclidean) distance between the two solutions at time (t, k) is given by

$$d(t, k) = \begin{cases} \varepsilon, & t \in [k, k + 1 - \varepsilon], \\ (1 - \varepsilon), & t \in [k + 1 - \varepsilon, k + 1]; \end{cases}$$

in other words, choosing $\varepsilon > 0$ as small as desired, arbitrarily close initial conditions generate trajectories which are apart by a finite amount (as close as desired to 1) during the arbitrarily small time intervals where $t \in [k + 1 - \varepsilon, k + 1]$. Since stability deals with trajectories remaining close forever and attractivity deals with trajectories getting closer and closer, examples such as the one above pose serious issues when defining (let alone establish) stability and attractivity in the hybrid case. Similar problems arise not only in output regulation problems but also in other areas like state tracking, observers, and general interconnections of hybrid systems.

However, intuition suggests (and mathematics confirms, by using a suitable notion of “distance”) that such trajectories are close indeed. Several approaches have been proposed in order to overcome such difficulty. Considering as an example a bouncing ball tracking another bouncing ball, the problematic time intervals are those between the bounce of the first ball hitting the ground and the bounce of the other ball; in such a case, the modified distances are defined by either

- Allowing to exclude sufficiently short “problematic” intervals (possibly requiring that their length asymptotically tends to zero); see, e.g., Galeani et al. (2008, 2012a)
- Considering alternative “mirrored” trajectories computed as if the last jump did not happen; see, e.g., Forni et al. (2013a)
- Using a “stretched” distance function δ such that when point a is in the jump set and its image via the jump map is $g(a)$, then $\delta(a, b) = \delta(g(a), b)$; see, e.g., Biemond et al. (2013).

While the first approach has been proposed first, the other two (which are strongly related) have the advantage of providing (under mild additional hypotheses) global control Lyapunov functions. Finally, it is worth noting that the most adequate tools to address similar issues for general hybrid systems are the “graphical distance” among hybrid arcs and related concepts (see Goebel et al. 2012b, Chap. 5).

Synchronous Jumps

When synchronous jumps are considered, the above issue disappears, and asymptotic stabilization becomes a much simpler matter. Although synchronous jumps look more like an exception than a rule in hybrid systems, they are very reasonable for specific classes of problems.

In order to have synchronous jumps, some authors have considered the use of “jump inputs” which *impose a jump at a certain time*, which can be physically reasonable in some systems, e.g., two tanks separated by a movable wall, assuming that when the wall is removed the fluid reaches the equilibrium configuration almost instantaneously.

Another relevant class consists of “sampled data” systems, whose jumps are essentially due to digital components which operate at a fixed sampling rate, which will be considered in the rest of this entry. In such a case, letting τ_M be the sampling period, the time domain of the hybrid system is fixed as (see Fig. 1)

$$\mathcal{T} := \{(t, k) : t \in [k\tau_M, (k+1)\tau_M], k \in \mathbb{Z}\}, \quad (3)$$

all jumps happen exactly for (t, k) with $t = (k+1)\tau_M$, and then (1) can be simplified as

$$\dot{w} = Sw, \quad (4a)$$

$$w^+ = Jw, \quad (4b)$$

and (2) can be simplified as

$$\dot{x} = Ax + Bu + Pw, \quad (5a)$$

$$x^+ = Ex + Rw, \quad (5b)$$

$$e = Cx + Qw, \quad (5c)$$

since flow and jump times are clear from the context.

For the latter class of systems, by using linear time-invariant hybrid control laws and observers (and an easily provable separation principle), it is easily shown that:

- Under a hybrid stabilizability hypothesis, state feedback stabilization of (5) is easily achieved.
- Output feedback stabilization of (5) from e is also trivial under an additional hybrid detectability hypothesis.
- Under hybrid detectability of the cascade of (4) and (5), w can be asymptotically estimated from e .

Due to the above facts, it can be assumed without loss of generality that (5) is asymptotically stable (equivalently, that all eigenvalues of $Ee^{A\tau_M}$ have modulus strictly less than one). Asymptotic stability then yields *incremental stability*, since letting $\hat{x}$ and $\check{x}$ denote two motions under the same inputs u, w and only differing in their initial states, it is immediate to see that their difference $\tilde{x} := \hat{x} - \check{x}$ evolves as

$$\dot{\tilde{x}} = \dot{\hat{x}} - \dot{\check{x}} = A\hat{x} + Bu + Pw$$

$$- (A\check{x} + Bu + Pw),$$

$$\tilde{x}^+ = \hat{x}^+ - \check{x}^+ = E\hat{x} + Rw - (E\check{x} + Rw),$$

that is, $\dot{\tilde{x}} = A\tilde{x}$, $\tilde{x}^+ = E\tilde{x}$, and so it is just a free motion of the plant, asymptotically converging to zero. Incremental stability implies that *regulation is achieved as soon as it is shown that for any exogenous input w it is possible to find an input u and an initial state of (5) such that e is identically zero*, since then any other motion arising from a different initial state will asymptotically converge to the motion with identically zero e . Moreover, it is easy to see that asymptotic stability of the origin actually implies uniform, global, and exponential stability of any trajectory for such systems.

Hybrid Steady-State Generation

From this point on, the rest of the presentation will be focused only on the case where the problem data are of the form (3) to (5), since this allows to provide an uncluttered view on some peculiar features of hybrid steady-state motions,

without the burden of having to take care of delicate stability issues arising in more general contexts.

Based on the preceding discussion, there is no loss of generality at this point in assuming that:

- *Plant (5) is asymptotically stable*, which is equivalent to all eigenvalues of $Ee^{A\tau_M}$ having a magnitude strictly less than one.
- *Exosystem (4) is Poisson stable*, which is equivalent to all eigenvalues of $Je^{S\tau_M}$ having a magnitude equal to one.

It is also customary to distinguish between *full information* and *error feedback* regulation, where in the first case controller, $\mathcal{C}$ has access to the complete state (w, x) of the cascade of $\mathcal{E}$ and $\mathcal{P}$, whereas in the second case, $\mathcal{C}$ can only measure the output e of $\mathcal{P}$.

Having assumed asymptotic stability of plant $\mathcal{P}$, the only role of compensator $\mathcal{C}$ consists in generating the correct steady-state input, since then, by incremental stability of $\mathcal{P}$, asymptotic regulation is ensured from any initial state. Recalling the expression of $\mathcal{T}$ in (3), for the following developments, it is useful to define the jump times t_k and the elapsed time of flow since last jump σ as

$$t_k := k\tau_M, \quad \sigma(t, k) := t - k\tau_M;$$

the arguments of $\sigma(t, k)$ will usually be omitted since clear from the context. Note that σ satisfies $\dot{\sigma} = 1$, $\sigma^+ = 0$, and it is often explicitly introduced as an additional *timer* variable.

The Full Information Case

Consider the full information regulator:

$$u(t, k) = \Gamma(\sigma)w(t, k) \quad (6)$$

and the candidate steady-state motion and input:

$$\begin{bmatrix} x_{ss}(t, k) \\ u_{ss}(t, k) \end{bmatrix} = \begin{bmatrix} \Pi(\sigma) \\ \Gamma(\sigma) \end{bmatrix} w(t, k). \quad (7)$$

Requiring that such expressions actually characterize a response of the considered plant, and that the associated output is zero, amounts to ask that:

- during flows, $\dot{x}_{ss}(t, k)$ has to satisfy the two equations:

$$\begin{aligned} \dot{x}_{ss}(t, k) &= \dot{\Pi}(\sigma)w(t, k) + \Pi(\sigma)\dot{w}(t, k), \\ \dot{x}_{ss}(t, k) &= Ax_{ss}(t, k) + Bu_{ss}(t, k) \\ &\quad + Pw(t, k); \end{aligned}$$

- at jumps, $x_{ss}^+(t, k)$ has to satisfy the two equations:

$$\begin{aligned} x_{ss}^+(t_{k+1}, k) &= \Pi(0)w^+(t_{k+1}, k), \\ x_{ss}^+(t_{k+1}, k) &= Ex_{ss}(t_{k+1}, k) + Rw(t_{k+1}, k); \end{aligned}$$

- for the output e_{ss} to be identically zero:

$$0 = Cx_{ss}(t, k) + Qw(t, k).$$

Substituting (7) in the above conditions and considering that such relations should hold for all values of w , the following *hybrid regulator equations* are obtained:

$$\dot{\Pi}(\sigma) + \Pi(\sigma)S = A\Pi(\sigma) + B\Gamma(\sigma) + P, \quad (8a)$$

$$\Pi(0)J = E\Pi(\tau_M) + R, \quad (8b)$$

$$0 = C\Pi(\sigma) + Q. \quad (8c)$$

Equations (8) are necessary and sufficient for (7) to solve the output regulation problem under the considered assumptions. Once a solution of (8) is available, the full information regulator (6) is just a time-varying static feedforward controller which provides as input the steady-state input u_{ss} characterized as in (7); in fact, since (5) is incrementally stable (as follows from its asymptotic stability, which was assumed without loss of generality), its output response under the control law (6) must converge to the output response associated to (7).

For later use, note that in the non-hybrid case where $\mathcal{P}$ and $\mathcal{E}$ only flow

$$\dot{w} = Sw, \quad (9a)$$

$$\dot{x} = Ax + Bu + Pw, \quad (9b)$$

$$e = Cx + Qw, \quad (9c)$$

the candidate steady state (7) is replaced by

$$\begin{bmatrix} x_{ss}(t) \\ u_{ss}(t) \end{bmatrix} = \begin{bmatrix} \Pi \\ \Gamma \end{bmatrix} w(t), \quad (10)$$

and (8) reduces to the celebrated *regulator equations* (or *Francis equations*)

$$\Pi S = A\Pi + B\Gamma + P, \quad (11a)$$

$$0 = C\Pi + Q, \quad (11b)$$

and, as above, assuming without loss of generality that the plant is asymptotically stable, the full information regulator reduces to the time-invariant static feedforward controller:

$$u(t, k) = \Gamma w(t, k). \quad (12)$$

The Error Feedback Case

If the exosystem's state is not measured, a *dynamic* compensator $\mathcal{C}$ is introduced, described by

$$\dot{\xi} = F\xi + Ge, \quad (13a)$$

$$\xi^+ = L\xi, \quad (13b)$$

$$u = H\xi. \quad (13c)$$

This compensator is also supposed to flow and jump according to the a priori fixed time domain $\mathcal{T}$ considered for the plant. The candidate steady-state motion including ξ is

$$\begin{bmatrix} x_{ss}(t, k) \\ \xi_{ss}(t, k) \\ u_{ss}(t, k) \end{bmatrix} = \begin{bmatrix} \Pi(\sigma) \\ \Sigma(\sigma) \\ \Gamma(\sigma) \end{bmatrix} w(t, k). \quad (14)$$

Mimicking previous arguments, that is, imposing that (14) is a response associated with zero output e , leads to the conclusion that (8) must be complemented with:

$$\dot{\Sigma}(\sigma) + \Sigma(\sigma)S = F\Sigma(\sigma), \quad (15a)$$

$$\Sigma(0)J = L\Sigma(\tau_M). \quad (15b)$$

$$\Gamma(\sigma) = H\Sigma(\sigma), \quad (15c)$$

Equations (8) and (15) are necessary and sufficient for (13) to solve the output regulation problem under the considered assumptions; they generalize the corresponding conditions for the non-hybrid case where $\mathcal{P}$ and $\mathcal{E}$ only flow (see (9)) and (13) and (14) are replaced by

$$\dot{\xi} = F\xi + Ge, \quad (16a)$$

$$u = H\xi, \quad (16b)$$

$$\begin{bmatrix} x_{ss}(t) \\ \xi_{ss}(t) \\ u_{ss}(t) \end{bmatrix} = \begin{bmatrix} \Pi \\ \Sigma \\ \Gamma \end{bmatrix} w(t), \quad (16c)$$

and (15) reduces to

$$\Sigma S = F\Sigma, \quad (17a)$$

$$\Gamma = H\Sigma. \quad (17b)$$

Relations (17) are an expression of the *internal model principle*, stating that in order to achieve error feedback regulation, the compensator $\mathcal{C}$ must include a suitable “copy” of the exosystem, enabling $\mathcal{C}$ to reproduce the signal $u_{ss} = \Gamma w$ (used in the full information case) as $u_{ss} = H\Sigma\xi$, without measuring w ! More specifically (denoting by M' , $\text{Im}(M)$, the transpose and the image of matrix M), Eq. (17b) requires that $\text{Im}(\Gamma') \subset \text{Im}(\Sigma')$, namely, that the row space of Σ is “sufficiently rich”; in turn, (17a) is a homogeneous Sylvester equation whose solution Σ can be nonzero if and only if F and S have common eigenvalues (hence, F must “copy” S , and the larger the $\text{Im}(\Sigma')$, the more common eigenstructure must be shared between F and S). A similar interpretation holds for (15), which expresses the *hybrid internal model principle*.

Key Features in Hybrid vs Classical Output Regulation

While the previous section mainly aimed at showing how the classical theory generalizes in the hybrid case (at least for a special class of hybrid systems), the aim of this section is to point out some of the striking differences between the two cases. Before proceeding further, and in order to keep focus on the characterization of the steady-state response, it is worth mentioning here that although time-varying systems will be considered, no issue regarding nonuniform stability (like in general nonautonomous systems) arises since the timer σ just ranges in the compact set $[0, \tau_M]$ due to the assumed periodic structure of $\mathcal{T}$ (see also the end of section “Synchronous Jumps”).

Comparing the classical and the hybrid output regulator and considering that $\mathcal{P}$ and $\mathcal{E}$ are time invariant, it seems somewhat strange that in the output feedback case, the linear time-invariant regulator (16a) and (16b) generalizes to a hybrid linear time-invariant regulator (13), whereas in the full information case, the linear time-invariant regulator (12) generalizes to a hybrid linear *time-varying* regulator (6).

One argument in favor of the *time-varying* regulator (6) is based on the following consideration. It is well-known that (11) has a unique solution in the case of a square plant ($m = p$) under the *nonresonance condition* between the zeros of $\mathcal{P}$ and the eigenvalues of $\mathcal{E}$, requiring that

$$\text{rank} \begin{bmatrix} A - sI & B \\ C & 0 \end{bmatrix} = n + p, \quad \forall s \in \Lambda(S),$$

where $\Lambda(S)$ denotes the spectrum of S . In such a case, (11) amounts to a system of $nq + pq$ linear equations in $nq + mq$ unknowns (the elements of Π, Γ), which might be expected to be satisfied since $m \geq p$. If one were trying to use the unique constant solution (Π, Γ) of (11) as a solution of (8), clearly (8a) and (8c) would be satisfied, but then (8b) would impose other nq equations on Π which would unlikely be satisfied. For this reason, apparently, the additional degree of freedom offered by choosing time-dependent Π

and Γ might be of help. In fact, it can be shown that if $m = p$ and under a hybrid nonresonance condition (involving $Ee^{A\tau_M}$ and $Je^{S\tau_M}$) between $\mathcal{P}$ and $\mathcal{E}$, (8a) and (8b) have a unique solution for any choice of $\Gamma(\sigma)$, so that the design boils down to satisfying (8c) by choosing $\Gamma(\sigma)$; but is this always possible? In order to answer this nontrivial question, a different path must be followed. While a complete formal analysis can be performed, the following discussion will be mainly based on showing the simplest examples exhibiting the pathologies of interest.

Consider the system with $\tau_M = 1$ (so that $t_k = k$, for all $k \in \mathbb{Z}$) and

$$\dot{w} = 0, \quad (18a)$$

$$w^+ = -w, \quad (18b)$$

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} -1 & 0 \\ 0 & -2 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u + \begin{bmatrix} 0 \\ 1 \end{bmatrix} w, \quad (18c)$$

$$\begin{bmatrix} x_1^+ \\ x_2^+ \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ 2e & 1 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}, \quad (18d)$$

$$e = \begin{bmatrix} 0 & 1 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} - w. \quad (18e)$$

The unique steady-state solution achieving output regulation is easily computed. By (18a) and (18b),

$$w(t, k) = (-1)^k w(0, 0);$$

then, by (18e), it appears that $e_{ss} = 0$, $\forall (t, k) \in \mathcal{T}$ implies

$$x_{2,ss}(t, k) = w(t, k) = (-1)^k w(0, 0),$$

$$\forall (t, k) \in \mathcal{T},$$

which in turn implies that $\dot{x}_{2,ss} = 0$ for all $t \in (k, k+1)$, $k \in \mathbb{Z}$ and the unique steady-state input

$$u_{ss} = 2x_{2,ss} - w.$$

Since (18d) implies that $x_{1,ss}(t_{k+1}, k+1) = x_{2,ss}(t_{k+1}, k) = w(t_{k+1}, k)$ and (18c) implies that $x_{1,ss}(t, k) = -e^{-(t-k)} x_{1,ss}(t_k, k)$, for $t \in$

(t_k, t_{k+1}) , it follows that

$$x_{1,ss}(t, k) = -e^{-(t-t_k)} w(t_k, k), \quad t \in (t_k, t_{k+1}), \quad (19)$$

which finally is coherent with the jump equation for $x_{2,ss}$ in (18d) since

$$\begin{aligned} x_{2,ss}(t_{k+1}, k+1) &= 2ex_{1,ss}(t_{k+1}, k) + x_{2,ss}(t_{k+1}, k) \\ &= 2e(-e^{-1})w(t_k, k) + w(t_k, k) \end{aligned} \quad (20a)$$

$$= -w(t_k, k) \quad (20b)$$

$$= (-1)^{k+1} w(0, 0). \quad (20c)$$

Before commenting the meaning of the above derived steady-state evolution, it is worth noting that (18) might actually derive from an original system with (18c) replaced by

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} -1 & 0 \\ 1 & -2 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u + \begin{bmatrix} 0 \\ 1 \end{bmatrix} w, \quad (21)$$

under the preliminary state feedback

$$u = -x_1 + v. \quad (22)$$

Such a feedback renders the subspace $\{x : x_2 = 0\}$ unobservable (when the system only flows) and reveals that the dynamics of x_1 in (18c) is the *flow zero dynamics* of $\mathcal{P}$, that is, the zero dynamics of $\mathcal{P}$ when jumps are inhibited. Having set the stage, several interesting observations can be made now.

The flow zero dynamics samples the exogenous signal w at jumps and then evolves according to its own modes (see (19)). In fact, while in the classical case (10), the state and input at steady state can be expressed as a constant matrix times the current value of w , the real nature of the time dependence of Γ and Π in (7) is linked to this phenomenon of *sampling* $w(t_k, k)$ and *propagating along the zero dynamics*. A suitable analysis shows that $\Pi(\sigma)$ and $\Gamma(\sigma)$ contain products of matrices with rightmost factor $e^{-S\sigma}$ (which recovers $w(t_k, k) = e^{-S\sigma} w(t, k)$ from the current value $w(t, k)$ of w) and leftmost factor containing the fundamental matrix of the flow

zero dynamics. It is worth mentioning that the “motion along the zeros” in the present context is strongly related to the same kind of motions used for perfect tracking in non-hybrid systems. The above insight about the nature of the dependence on σ in (7) also reveals why in the output feedback case (13) such dependence is not needed: the required modes of the flow zero dynamics in that case are provided by copying them in the compensator dynamics!

An even stronger consequence of the analysis above is a **flow zero dynamics internal model principle**, which essentially states that any output feedback compensator solving the output regulation problem must be able to produce as free responses (during flow) a suitable subset of the natural modes of the flow zero dynamics (and a suitably modified version applies to the feedforward static compensator (6)). Note that while the *classical internal model principle* requires only *exact knowledge of the exosystem modes* (which is kind of a mild requirement, especially when the exosystem models references, or constant offsets), the *flow zero dynamics internal model principle* requires the *exact knowledge of the modes of the flow zero dynamics*, which typically depends on unknown plant parameters; clearly, this fact is a serious obstruction to achieve robust regulation. To date, three approaches have been proposed to deal with this obstruction; in order of increasing generality and complexity, they are:

- (i) assume that the modes of the flow zero dynamics are unaffected by parameter variations;
- (ii) assume that the flow zero dynamics is decoupled during flows;
- (iii) use an adaptive internal model tuned on an online estimate of the modes of the flow zero dynamics.

The solution in (i), proposed in Marconi and Teel (2013) (and adopted in subsequent works by the same authors, e.g., Cox et al. (2016)), implies both *structurally restricted* and *coordinated* plant parameter variations (such that if one parameter changes, the other parameters also have to change to keep the modes of the flow

zero dynamics fixed). The solution in (ii), proposed in Carnevale et al. (2017), only imposes another kind of *structurally restricted* variations, often satisfied in physical systems where the flow zero dynamics is actually associated to a part of the system that only interacts at jumps but is decoupled during flows; the parameters are otherwise allowed to vary independently. Finally, the solution in (iii), proposed in de Carolis et al. (2020), solves the general problem, imposing no restriction on plant parameter variations but requiring an essentially nonlinear compensation.

A final point, also raising serious issues about what can be robustly achieved (and how) in the setting of hybrid output regulation, is the fact that **generically, existence of solutions is not robust to arbitrarily small parameter variations**. In particular, looking again at the computations in (20), it should be clear that the involved functions are all fixed by previous reasonings, whereas satisfaction of (20) crucially depends on exact cancellations of certain coefficients. Any small variations of such coefficients in (18d) imply that the problem admits no steady state yielding zero output. This fact is in sharp contrast with classical regulation, where the nonresonance condition ensures existence of (different) solutions for small parameter variations. It has to be noted, though, that **under additional conditions, robust existence of solutions is guaranteed if the plant is fat**, that is, $m > p$. Using again the previous example, this is the case if an additional input is introduced

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} -1 & 0 \\ 0 & -2 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} w,$$

since then even a constant (suitably chosen) value of u_1 can be used to ensure that when the time to jump arrives, the value of x_1 is such to ensure a correct jump for x_2 (remember that since x_1 is unobservable during flows, its motion can be changed as wished if this helps with ensuring that the observable x_2 achieves zero output). Again, if *structurally restricted* and *coordinated* plant parameter variations are considered, the problem can be addressed for square systems as in Marconi and Teel (2013) and Cox et al. (2016); for

general parameter variations, fat plants have to be considered with the approach in Carnevale et al. (2017) and de Carolis et al. (2020).

Summary and Future Directions

The investigation of the output regulation problem for hybrid systems is still at a very early stage. While the issues of stabilization of the manifold where regulation is achieved seem to be a relatively better understood topic (possibly drawing from a richer literature on stabilization of hybrid systems), the geometry and design of such manifold appear to involve several much more intricate issues, whose understanding will be crucial in order to achieve more complete solutions.

Already in the very simplified case of linear dynamics and synchronous jumps, the important role played by the whole flow zero dynamics for feasibility (existence of solutions in the nominal parameter values) and by the availability of more inputs than outputs for well posedness (existence of solutions for slightly perturbed parameter values) marks a strong difference with the linear non-hybrid case, where both properties are granted by satisfaction of the nonresonance condition, which only involves the spectrum of the zero dynamics, even for square plants.

While the expected final goal of this investigation should hopefully lead to the design of robust output regulators based on a suitable internal model principle, a deeper understanding of the structure of the steady-state motion achieving regulation, as well as of the effect of additional inputs in shaping it, seems to be an important preliminary step toward such goal.

Parallel Robots

Frank C. Park
Robotics Laboratory, Seoul National University,
Seoul, Korea

Abstract

Parallel robots are closed chains consisting of a fixed and moving platform that are connected by a set of serial chain legs. Parallel robots typically possess both actuated and passive joints and may even be redundantly actuated. Although more structurally complex and possessing a smaller workspace, parallel robots are usually designed to exploit one or more of the natural advantages they possess over their serial counterparts, e.g., higher stiffness, increased positioning accuracy, and higher speeds and accelerations. In this chapter we provide an overview of the kinematic and dynamic modeling of parallel robots, a description of their singularity behavior, and basic methods developed for their control.

Keywords

Closed kinematic chain · Closed loop mechanism · Parallel manipulator

Introduction

A parallel robot refers to a kinematic chain in which a fixed platform and moving platform are connected to each other by several serial chains, or legs. The legs, which typically have the same kinematic structure, are connected to the fixed and moving platforms at points that are distributed in a geometrically symmetric fashion. The Stewart-Gough platform (Fig. 1) is a well-known example of a parallel robot: each of the six legs is a *UPS* structure (i.e., consisting of rigid links serially connected by a universal, prismatic, and spherical joint), with the prismatic joint actuated. Other examples of parallel robots include the $6 \times RUS$ platform of Fig. 2, the haptic interface device of Fig. 3, and the eclipse mechanism of Fig. 4.

Parallel robots can be regarded as a special class of closed chain mechanisms (i.e., chains that contain one or more closed loops) and are purposely designed to exploit the specific advantages afforded by the closed chain structure, e.g., for improved stiffness, greater positioning accuracy, or higher speed. Parallel robots should be distinguished from two or more cooperating serial robots that may form closed loops during execution of a task (e.g., a robotic hand grasping an object). Some of the fastest velocities and accelerations recorded by industrial robots have been achieved by parallel robots, primarily by

placing the actuators on the fixed platform and thereby minimizing the mass of the moving parts.

Many of the model-based techniques developed for the control of traditional serial chain robots are also applicable to a large class of parallel robots. On the other hand, kinematic and dynamic models for parallel robots are inherently more complex. Parallel robots also possess features not found in serial robots, e.g., passive joints, the possibility of redundant actuation, and a diverse range of singularity behavior, that need to be considered when designing a control law. We therefore begin with a brief

overview of the kinematic and dynamic modeling of parallel robots before discussing their control.

Modeling

Kinematics

Whereas the kinematic degrees of freedom, or mobility, of a serial chain robot can be obtained as the sum of the degrees of freedom of each of the joints, the situation is somewhat more complex for parallel robots and closed chains in general, since only a subset of the joints can be independently actuated. The mobility of a parallel robot corresponds to the total degrees of freedom of the joints that can be independently actuated. In some cases the number of actuated joint degrees of freedom may exceed the kinematic degrees of freedom, in which case we say that the robot is redundantly actuated.

A parallel robot with a designated end-effector frame also has a notion of forward and inverse kinematics. While for serial chains the forward kinematics is a well-defined mapping and the inverse kinematics can typically have multiple solutions, for parallel robots the situation is less straightforward. For the Stewart-Gough platform of Fig. 1, in which the leg lengths can be adjusted by actuating the prismatic joints, the inverse

Parallel Robots, Fig. 1 Stewart-Gough platform

Parallel Robots, Fig. 2 $6 \times RUS$ platform

Parallel Robots, Fig. 3 A $3 \times PUU$ haptic interface

Parallel Robots, Fig. 4 The $3 \times PPRS$ eclipse parallel mechanism

kinematics is unique and straightforward to obtain, whereas the forward kinematics will have multiple solutions. For other types of parallel robots in which the legs themselves contain one or more closed loops, both the forward and inverse kinematics can have multiple solutions.

The notion of kinematic singularities for parallel robots is also much more involved than the case for serial robots. Whereas kinematic singularities for serial chain robots are characterized by configurations at which the forward kinematics Jacobian (i.e., the linear mapping relating joint velocities to end-effector frame velocities)

becomes singular, for parallel robots and closed chains in general, there exist other notions of singularities not found in serial chains. For example, given a parallel robot with kinematic mobility m – if the parallel robot consists only of one degree-of-freedom joints, this implies that exactly m joints can be actuated – there may exist configurations in which these m joints cannot be independently actuated. Conversely, even if the m actuated joints are each fixed to some value, the parallel robot may fail to be a structure, i.e., some of the links may be able to move.

In the above scenario, choosing a different set of m actuated joints may remedy this situation, in which case such singularities are referred to as actuator singularities. Configurations at which singularity behavior occurs regardless of which joints are actuated are denoted configuration singularities. The final class of singularities are end-effector singularities, which correspond to the usual serial chain notion of kinematic singularity, in which the end-effector loses one or more degrees of freedom of available motion.

Dynamics

In the case of a parallel robot whose actuated degrees of freedom coincides with its kinematic mobility m , it is possible to choose an independent set of generalized coordinates of dimension m , denoted $q \in \mathbb{R}^m$ and typically identified with the actuated joints, and to express the dynamics in the standard form

$$M(q)\ddot{q} + C(q, \dot{q})\dot{q} + G(q) = \tau, \quad (1)$$

where $\tau \in \mathbb{R}^m$ denotes the vector of input joint torques, $M(q)$ denotes the $n \times n$ mass matrix, the matrix-vector product $C(q, \dot{q})\dot{q}$ denotes the vector of Coriolis terms, and $G(q) \in \mathbb{R}^m$ denotes the vector of gravitational forces. The structure of the dynamic equations is identical to that for serial chain robots. Also like the case for serial chain robots, the Coriolis matrix term $C(q, \dot{q}) \in \mathbb{R}^{m \times m}$ is not unique, so that one should ensure that the correct $C(q, \dot{q})$ is used in, e.g., any control law whose stability depends on the matrix $\dot{M}(q) - 2C(q, \dot{q})$ being skew-symmetric.

It is also important to keep in mind that the q must satisfy the kinematic constraint equations imposed by the loop closure constraints. That is, if $\theta \in \mathbb{R}^n$ denotes the vector of all joints (both actuated and passive), then $q \in \mathbb{R}^m$, $m \leq n$, will be a subset of θ whose values can only be obtained by solution of the kinematic constraint equations; depending on the nature of the kinematic constraints, one may have to resort to iterative numerical methods.

If the parallel robot is redundantly actuated, then the dynamics are subject to a further set of constraints on the input torques. Letting q_e denote the set of independent generalized coordinates and q_a be the vector of all actuated joints, the vector of actuated joint torques τ_a must then further satisfy $S^T \tau_a = W^T \tau$, where τ denotes the vector of joint torques for an equivalent tree structure system that moves identically to the redundantly actuated parallel robot and W and S are defined, respectively, by

$$S = \frac{\partial \theta}{\partial q_e}, \quad W = \frac{\partial q_a}{\partial q_e}. \quad (2)$$

Compared to the dynamics for serial chain robots, the dynamics for parallel robots is, in general, considerably more complex and computationally involved. The recursive algorithms that are available for computing the inverse and forward dynamics of serial chain robots can also be used to develop similar recursive algorithms for parallel robot dynamics; however, the computations will be considerably more involved and require multiple iterations.

Motion Control

Exactly Actuated Parallel Robots

For parallel robots whose actuated degrees of freedom match the kinematic mobility (this excludes the set of all redundantly actuated parallel robots), most control laws developed for serial chain robots are also applicable. This is not altogether surprising in light of the similarity in the structure of the kinematic and dynamic equations between serial and parallel robots.

Control laws for serial robots are also covered in this handbook, and we refer the reader to ► [Linear Matrix Inequality Techniques in Optimal Control](#) for the essential details. Here we summarize the most basic control laws and point out any additional computational or other requirements that are needed when applying these laws to parallel robots. Note that other control laws and techniques developed for serial chain robots, e.g., robust, sliding mode, can also be applied with the same additional considerations and requirements outlined below:

1. **Computed torque control:** Computed torque control for parallel robots has the same control law structure as for serial robots, i.e.,

$$\tau = M(q) (-K_p e - K_v \dot{e}) + \tau_{ff}, \quad (3)$$

where e denotes the tracking error, K_p and K_v are the proportional and derivative feedback gain matrices, and τ_{ff} denotes the feed-forward term required to cancel the nonlinear dynamics. Robust versions of computed torque control are also applicable to parallel robots under the same set of conditions, e.g., establishing appropriate bounds on the mass matrix eigenvalues and on the norm of the Coriolis matrix.

2. **Augmented PD control:** The augmented PD control law for serial robots is also applicable to parallel robots, i.e.,

$$\tau = -K_p e - K_v \dot{e} + M(q) \ddot{q}_d + C(q, \dot{q}) \dot{q} + G(q), \quad (4)$$

where q_d is the reference trajectory to be tracked and K_p and K_v are the proportional and derivative feedback gains. Asymptotic stability is also established under the same conditions.

3. **Adaptive control:** Because the dynamic equations for parallel robots are also linear in the link mass and inertial parameters, i.e.,

$$M(q) \ddot{q} + C(q, \dot{q}) \dot{q} + G(q) = \Phi(q, \dot{q}, \ddot{q}) p, \quad (5)$$

where p denotes the vector of link mass and inertial parameters, adaptive control laws developed for serial robots can also be used.

4. **Other control methods:** There exist numerous control methods developed for serial robots, e.g., task space or operational space control, sliding mode control, and various nonlinear control techniques; with few exceptions most of these algorithms can also be applied to exactly actuated parallel robots with minimal modification.

Redundantly Actuated Parallel Robots

As described earlier, parallel robots exhibit a much more diverse range of singularity behavior than their serial counterparts, many of which depend on the choice of actuated joints (actuator singularities). One way to eliminate actuator singularities is via redundant actuation, i.e., the total degrees of freedom of the actuated joints exceeds the kinematic mobility of the mechanism. Redundant actuation offers some protection in the event of failed actuators and, when combined with an appropriate control law, offers an effective means of reducing joint backlash, increasing speed and payload and stiffness, controlling compliance through the generation of internal forces, and even improving power efficiency (as an analogy, the human musculoskeletal system is redundantly actuated by antagonistic muscles). Of course, redundant actuation introduces a new set of control challenges, since the control inputs must be designed so as not to conflict with the kinematic constraints inherent in the parallel robot; loosely speaking, the actuated joints can no longer be independently controlled, since the consequences of unintended antagonistic actuation may be catastrophic.

The control of cooperating manipulators (see ► [Optimal Control and Mechanics](#)) has a long history in robotics, and many of the control techniques developed for such multi-arm systems can also be applied to redundantly actuated parallel robots. One can also apply the control strategies developed for exactly actuated parallel robots to the redundantly actuated case, but modifications are necessary to account for the different structure of the dynamic equations.

Like all model-based control algorithms, the above control laws are subject to model uncertainties. Whereas in serial chains the effects of model uncertainty simply lead to errors in tracking, for redundantly actuated parallel robots, the consequences can lead to internal forces in addition to end-effector tracking errors. Perhaps the most significant effect of any modeling errors is that, unlike the serial chain case, the kinematic errors can potentially alter the shape of the configuration space (recall that the configuration space will in general be a curved space for closed chains) and also interfere with any PD feedback introduced into the control. The development of control laws that are robust to such modeling errors and disturbances remains an open and ongoing area of research in parallel robot control.

Force Control

Both hybrid force-position control and impedance control are well-known and widely applied concepts in serial robots and can be extended in a straightforward manner to exactly actuated parallel robots. Recall that the basic feature of hybrid force-position control is that the task space is decomposed into force- and position-controlled directions, whereas in impedance control, the goal is have the robot maintain a certain desired spatial stiffness in the task space. Controllers that combine aspects of force-position and impedance control have also been proposed and developed for both serial robots and exactly actuated parallel robots. Modeling errors will cause deviations in both the force- and position-controlled directions – leading to motions in force-controlled directions and forces in position-controlled directions – which can be addressed by, e.g., a switching control strategy.

The problem of force control for redundantly actuated parallel robots, which encompasses both force-position and impedance control, has also received some attention in the literature. The main difference with the exactly actuated case is that internal forces can now be generated,

which requires a more detailed and coordinate-invariant examination of stiffness. Control methods that combine elements of force-position and impedance control for redundantly actuated parallel robots have received only limited attention in the literature.

Particle Filters

Fredrik Gustafsson

Electrical Engineering, Linköping University,
Linköping, Sweden

Abstract

The particle filter computes a numeric approximation of the posterior distribution of the state trajectory in nonlinear filtering problems. This is done by generating random state trajectories and assigning a weight to them according to how well they predict the observations. The weights are instrumental in a resampling step, where trajectories are either kept or thrown away. This exposition will focus on explaining the main principles and the main theory in an intuitive way, illustrated with figures from a simple scalar example. A real-time application is used to graphically show how the particle filter solves a nontrivial nonlinear filtering problem.

filtering · Sequential Monte Carlo

Introduction

The particle filter computes an arbitrarily good solution to nonlinear filtering problems. The goal in nonlinear filtering is to compute the posterior distribution of the state vector in a dynamic model, given measurements that are related to the state. Bayes rule provides a recursive but computationally intractable solution. Monte Carlo (MC) methods can essentially solve all Bayesian inference problems. However, for nonlinear filtering, the complexity

increases exponentially in time. The MC approach would be to generate a large number of state trajectories (called particles) and their corresponding sequences of predicted measurements and then weighs together the trajectories according to how well the predicted and actual measurement sequences match each other.

With increasing time, the fit is deemed to be poor, since the state space increases exponentially in time. This is usually referred to as the depletion (or degeneracy) problem. The approach in the particle filter is to simulate only one step at the time and then resample the trajectories if needed. For this reason, the particle filter is sometimes referred to as a sequential Monte Carlo method. The resampling step keeps the trajectories that give a good fit, while the bad ones are discarded. The novel idea in the particle filter when it was first published in 1993 was the introduction of this resampling step.

Depletion is still a problem, despite the resampling step. Mitigating depletion has ever since the beginning been the most pressing issue in applied particle filtering. This tutorial will present the basic particle filter algorithm and discuss ways to avoid depletion problems both in general terms and in a simple example.

The particle filter computes an approximation to the Bayes optimal filter, conditioned on a sequence of observations and a nonlinear non-Gaussian system. It is important to note that the PF approximates the posterior distribution of the state trajectory, from which the mean and covariance are easily extracted. In contrast, the extended Kalman filter (EKF) computes the mean and covariance for an approximate dynamical system (linearized with Gaussian noise). The unscented Kalman filter (UKF) likewise also approximates the mean and covariance. Both EKF and UKF can only approximate unimodal (one peak) posterior distributions. There are filter bank approximations, like the interacting multiple model (IMM) algorithm, that can keep track of a given number of modes in the posterior. However, the PF does this in a more natural way.

The Basic Particle Filter

Nonlinear filtering aims at estimating the distribution of a state sequence $x_{1:N} = (x_1, x_2, \dots, x_N)$ from a sequence of observations $y_{1:N} = (y_1, y_2, \dots, y_N)$, given a state space model of the form

$$x_{k+1} = f(x_k, v_k) \quad \text{or} \quad p(x_{k+1}|x_k), \quad (1a)$$

$$y_k = h(x_k, e_k) \quad \text{or} \quad p(y_k|x_k). \quad (1b)$$

Here, v_k denotes process noise, and e_k is the measurement noise. The stochastic variables v_k, e_k for all k and x_0 are assumed mutually independent, with known distributions p_v, p_e , and p_{x_0} , which are all being part of the model specification.

The particle filter (PF) works with a set of random trajectories. Each trajectory is formed recursively by iteratively simulating the model with some randomness and then updating the likelihood of each trajectory based on the observation. In words, we first evaluate the set of particles at hand by comparing how well they predict the current observation. In this way, the particles are assigned a weight. We keep the particles with large weight and throw away the particles with small weight, using a stochastic resampling procedure. After this step, we get a smaller set of particles, where many particles have several replicas. We then simulate each particle to the next observation time using the dynamical model. After this prediction step, all particles will be unique (because they are based on different realizations of the process noise). Below, the basic algorithm (sometimes called bootstrap PF or sequential importance resampling (SIR) PF) is summarized.

- Define a set of random states (particles) by sampling $x_0^{(i)} \sim p_{x_0}(x_0)$.
- Iterate in $k = 0, 1, \dots$:

- 1 Measurement update: Compute the weight $\omega_k^{(i)} = p_e(y_k - h(x_k^{(i)}))$ and normalize so $\sum_{i=1}^N \omega_k^{(i)} = 1$.

- 2 Resampling: Resample each particle with probability $\omega_k^{(i)}$.
- 3 Time update: Simulate one time step by taking $v_k^{(i)} \sim p_v(v_k)$ and then set $x_{k+1}^{(i)} = f(x_k^{(i)}, v_k^{(i)})$.

The main design parameter here is the number N of particles. A common trick to make the filter more robust is to increase the variance of p_v and p_e above. This is called dithering (or jittering) and is a practical way to get more robust nonlinear filters.

To illustrate some of the aspects and for later reference, a simple example will be introduced.

Example: First-Order Linear Gaussian Model

The Kalman filter (KF) provides the posterior distribution in an analytical form for linear Gaussian models and is thus suitable for evaluations and comparisons. A linear Gaussian model looks like

$$x_{k+1} = Fx_k + v_k, \quad v_k \sim N(0, Q). \quad (2a)$$

$$y_k = Hx_k + e_k, \quad e_k \sim N(0, R), \quad (2b)$$

$$x_0 \sim N(\mu_0, P_0), \quad (2c)$$

We will use the scalar case for the illustrations, and the figures that follow are based on $F = 0.9$, $H = 1$, $Q = 1$, $R = 0.01$, $P_0 = 1$. The particle filter in the scalar case simplifies to the Matlab algorithm in Table 1. Figure 1 compares the sample-based representation of the PF with the Gaussian distribution provided by the KF for the first two time steps. This shows how well the marginal distribution $p(x_k|y_{1:k})$ is approximated by the samples $x_k^{(i)}$ from the PF. A rule of thumb is that 30 samples are needed to approximate a univariate Gaussian distribution. As will be discussed later, the number of samples is effectively only 10 here, which explains the small deviation of the Gaussian functions.

Particle Filters, Table 1 Matlab code for scalar linear Gaussian model

```
% Simulation

        sqrt(Q)*randn(N-1,1)]+sqrt(R)*randn(N,1);
% Particle filter
x=mu0+sqrt(P0)*randn(N,1);
for k=1:K
    w=exp(-(y(k)-H*x).^2/R);           % Measurement update
    w=w/sum(w);                       % Normalization
    xhat(k)=w'*x;                     % Estimate
    P(k)=w'*(x-xhat(k)).^2;           % Variance
    x=resample(x,w);                  % Resampling
    x=F*x+sqrt(Q)*randn(N,1);         % Time update
end
```

Particle Filters, Fig. 1 Set of samples $\{x_k^{(i)}\}_{i=1:N}$ compared to first a Gaussian approximation of the particles (blue) and second to the true posterior distribution provided by the Kalman filter (green)

To illustrate the fundamental depletion problem in the PF, the set of trajectories $x_{1:k}^{(i)}$ that approximates the posterior (smoothing) distribution $p(x_k | y_{1:k})$ is illustrated in Fig. 2. The upper plot shows a case where the trajectories are all the same initially. The behavior in the upper plot is typical for the basic particle filter in cases where the measurements are more informative than the state transition model (small measurement noise, $R < Q$). The lower plot shows a particle filter that is working better, and

the modification is explained in the following section.

Proposal Distributions

The time update in the basic PF predicts particles in step 4 according to the dynamic model. The most general derivation of the particle filter allows for sampling from a more general proposal (also called importance) distribution. This proposal distribution can be any function that

Particle Filters, Fig. 2 Set of trajectories $\{x_{1:10}^{(i)} - x_{1:10}\}_{i=1:N}$ for two different proposal distributions, one bad one (prior) leading to particle depletion and one good

one (likelihood). Note that the smoothing distribution $p(x_k | y_{1:10})$ can be approximated with the set of particles $\{x_k^{(i)}\}_{i=1:N}$ using the marginalization principle

can be sampled from, and it can depend on both the previous state and the current measurement. From a filtering perspective, it may appear as “cheating” to look at the next measurement when doing the time update, but one has to look at a full cycle of the iteration scheme.

If a proposal distribution of the functional form $q(x_k | x_{k-1}, y_k)$ is used, then steps 1 and 3 have to be modified as follows:

- 1 *Weight update:* Time and measurement updates:

$$w_{k|k-1}^{(i)} \propto w_{k-1|k-1}^{(i)} \frac{p(x_k^{(i)} | x_{k-1}^{(i)})}{q(x_k^{(i)} | x_{k-1}^{(i)}, y_k)}, \quad (3a)$$

$$w_{k|k}^{(i)} \propto w_{k|k-1}^{(i)} p(y_k | x_k^{(i)}). \quad (3b)$$

- 3 *Prediction:* Generate samples from the proposal

$$x_{k+1}^{(i)} \sim q(x_{k+1} | x_k^{(i)}, y_{k+1}) \quad (3c)$$

The most natural proposal distributions are the following:

- The prior $q(x_{k+1} | x_k^{(i)}, y_{k+1}) = p(x_{k+1} | x_k^{(i)})$, as used in the basic PF.
- The likelihood $q(x_{k+1} | x_k^{(i)}, y_{k+1}) \propto p(y_{k+1} | x_{k+1})$. For the model (2), the proposal becomes $N(y_k/h, R_k/h^2)$.
- The optimal (minimizing weight variance) choice $q(x_{k+1} | x_k^{(i)}, y_{k+1}) \propto p(y_{k+1} | x_{k+1}) p(x_{k+1} | x_k^{(i)})$. For the model (2), the optimal proposal is provided by one cycle of the Kalman filter, initialized with the particle $x_k^{(i)}$.

The optimal proposal keeps the weights constant, and this would in theory avoid depletion, where depletion is interpreted as excessive weight variance. Figure 2 compares the set of trajectories for the prior and likelihood proposals, respectively. Apparently, the likelihood proposal is to prefer here, since it suffers less from depletion in the particle history. The practical limitation with the last two alternatives is that one has to be able to sample from the likelihood, so in practice there

needs to be more measurements than states in the model.

Adaptive Resampling

Resampling is crucial to avoid depletion. Without resampling, all trajectories except for one will get zero weight quite quickly. However, there is no need to resample at every iteration. Actually, resampling increases the weight variance, which is undesired. The question is how to decide if resampling is needed. The efficient number of particles estimated as

$$N_{\text{eff}}(k) = \frac{1}{\sum_{i=1}^N (w_{k|k}^{(i)})^2}, \quad (4)$$

is one suitable indicator. If all particles have the same weight $w_{k|k}^{(i)} = 1/N$, then $N_{\text{eff}}(k) = N$. Conversely, if one weight is one and all other zero, then $N_{\text{eff}}(k) = 1$. Thus, N_{eff} can be interpreted as a measure of how many particles that actually contribute to the solution.

Figure 3 shows the evolution of $N_{\text{eff}}(k)$ for prior and likelihood proposals, respectively. With resampling in every iteration, the likelihood proposal performs very well with $N_{\text{eff}}(k) \approx N$, while the prior proposal effectively uses only 10 % of the particles. Thus, $N_{\text{eff}}(k)$ is a good indicator of the quality of the proposal distribution.

In Fig. 1, $N = 100$ so effectively 10 samples are contributing to the Gaussian approximation, which as mentioned before is too small a number to get a good result.

As a comparison, Fig. 3 also shows N_{eff} if resampling is never used, then $N_{\text{eff}}(k)$ normally decreases over time. The likelihood proposal does not decrease as fast as the prior proposal, and for this very short data sequence resampling is really not needed at all.

In summary, resampling increases weight variance and decreases the performance of the filter. On the other hand, without resampling the effective number of particles converges monotonously to only one. So, the idea of adaptive resampling is natural. The key idea is to resample only if

the effective number of particles is small. The usual rule of thumb is that resampling is needed if $N_{\text{eff}}(k) < 2N/3$.

Resampling was the main contribution in Gordon et al. (1993) to get a working algorithm.

Marginalization

The posterior distribution approximation provided by the particle filter converges with the number of particles. In theory, the convergence rate is g_k/N , where g_k is a polynomial function in time k . In practice, it appears that the required number of particles increases very quickly with state dimension. Unless a very good proposal distribution is found, the practical limit for the state dimension is around 3–4 as a rough rule of thumb.

For applications with a large number of states, one can in many cases still use the particle filter. The idea is to find a linear Gaussian substructure in the model and then divide the state vector x_k into two parts: x_k^l for the states that appear linearly and x_k^n for the remaining states. Bayes rule provides the factorization

$$p(x_k^l, x_{1:k}^n | y_{1:k}) = p(x_k^l | x_{1:k}^n, y_{1:k}) p(x_{1:k}^n | y_{1:k}) \quad (5)$$

With a linear Gaussian substructure for x_k^l , given the whole trajectory $x_{1:k}^n$, then the Kalman filter applies and provides a Gaussian distribution for the first factor in (5). The second factor is resolved using a marginalization procedure so that the particle filter can be applied.

The bottom line is that each particle is associated with one Kalman filter. The method is called Rao-Blackwellized particle filter, or marginalized particle filter, in literature.

Illustrative Application: Navigation by Map Matching

A nontrivial application where the PF solves a nonlinear filtering problem, where Kalman filter-based approaches would fail, is described in

Particle Filters, Fig. 3 The efficient number of particles $N_{\text{eff}}(k)/N$ for prior proposal (blue) and likelihood proposal (green) ($N = 1,000$)

Forssell et al. (2002). The problem is to compute a robust estimate of the position of a car, without using infrastructure such as cellular networks or satellites. The approach is based on measuring wheel speeds on one axle and from that dead reckon a nominal trajectory using standard odometric formulas. A road map is then used as a measurement, to rule out impossible or unlikely maneuvers. There is no numeric measurement y_k in this approach, but the likelihood $p(y_k|x_k)$ in the model (1b) is large when x_k corresponds to a road position and decays quickly to zero outside the road network. Figure 4 illustrates the particle cloud gradually focuses around the true position with time. In particular, the number of modes in the posterior distributions is rather high initially, but decreases over time, in particular after each turn.

The particle filter is sometimes believed to be too computer intensive for real-time applications. As described in Forssell et al. (2002), this demonstrator implemented a particle filter on a pocket computer anno 2001 with $N = 15,000$ particles running in 10 Hz. Thus, the computational

complexity of the particle filter should not be overemphasized in practice.

Summary and Future Directions

The particle filter can be seen as a black-box solution to the nonlinear filtering problem, where any nonlinear dynamical model with arbitrary noise distributions can be plugged in. The main tuning parameter is the number of particles, and the PF will work in theory if this number is large enough. In practice, there are many tricks the user has to be aware of to mitigate the curse of dimensionality (depletion) that occurs for large state spaces (more than three) or long time sequences (more than a couple of samples). One engineering trick is dithering, to increase the variance in the involved noise distributions from their nominal values. More theoretical ways to mitigate depletion include clever choices of proposal distributions to sample from and marginalization (to solve a subset of the estimation problem with a Kalman filter).

Particle Filters, Fig. 4 Car navigation using wheel speed and a street map. The figures illustrate of how the particle representation of the position posterior distribution of position (course state is now shown) improves over time. After four turns, the posterior is essentially unimodal, and

a position marker can be shown. The *circle* denotes GPS position, which is only used for comparison. (a) After first turn. (b) After second turn. (c) After third turn. (d) After fourth turn

Current and future research directions include the issues above. A further trend concerns the related smoothing problem, which is interesting in itself, but which has turned out to be instrumental in joint state and parameter estimation problems. There are also many attempts to make the particle filter more robust, including ideas of filter banks and invoking a second layer of sampling algorithms to implement the proposal

distribution. There is also a trend to use the particle filter as a computational engine for more complex problems, such as the simultaneous localization and mapping (SLAM) problem, and to approximate the probability hypothesis density (PHD) for multi-sensor multi-target tracking. Finally, there are a large number of papers reporting on applications in traditional as well as new disciplines.

Passivity and Passivity Indices for Switched and Cyber-physical Systems

Hasan Zakeri and Panos J. Antsaklis
Department of Electrical Engineering,
University of Notre Dame, Notre Dame,
IN, USA

Abstract

Cyber-physical systems (CPS), in which the interactions with the environment are enabled by computational and communication components, pose great challenges in design and analysis for control engineers. The operation of these systems is monitored, coordinated, controlled, and integrated by a computing and communication core interacting with the physical world. Given the large scale of such systems, it is important to develop tools that can guarantee system level properties, such as stability, from the properties of individual components and their interactions. Passivity and dissipativity are energy-like concepts and widely used in control design. They quantify the “energy” consumption of a dynamical system and have shown great promise in the design of cyber-physical systems because of their *compositionality* properties (Antsaklis et al., *Eur J Control* 19(5):379–388, 2013). Passivity indices are measures of passivity and extend the applicability of passivity-based tools to nonpassive systems as well. In the present entry, an overview of applications of passivity and passivity indices in the design of cyber-physical systems is given. Passiv-

ity indices and passivation methods are also discussed for linear, nonlinear, hybrid, and networked systems.

Keywords

Passivity · Passivity indices · Dissipativity · Switched systems · Hybrid systems · Cyber-physical systems · Passivation

Introduction

This entry extends the discussion in the companion entry *Passivity, Dissipativity, and Passivity Indices* to the cases of switched and cyber-physical systems. Passivity-based tools have been studied for linear and nonlinear systems for a long time, but their extension to switched and cyber-physical systems is subject of recent research. This extension provides tools to analysis and design complex systems in a simpler manner.

Definitions of passivity indices and their basic properties given in the companion entry are extended here. Specific values of the passivity indices of a system can be assigned via compensation and can be used in design approaches that involve not only passive but also nonpassive systems. A review of design tools based on passivation is also included.

Passivation

Passivity indices can be adjusted by introducing gains in series, feedback, or parallel configurations. A general method is given in Xia et al. (2014) using an input-output transformation matrix. Appropriate design of this matrix, called here *the M-matrix*, guarantees desired passivity levels for the system. This transformation matrix allows the use of a nonpassive controller to guarantee the passivity and stability of a feedback control system. Consider the system G and a general input-output transformation matrix M as shown in Fig. 1. The matrix M is invertible and defined as

Passivity and Passivity Indices for Switched and Cyber-physical Systems, Fig. 1 M -matrix interconnection

$$M \triangleq \begin{bmatrix} m_{11}I & m_{12}I \\ m_{21}I & m_{22}I \end{bmatrix} \quad (1)$$

where m_{ij} are real scalars. It can be shown that the passivity indices of the system $\Sigma_0 : u_0 \rightarrow y_0$, defined via

$$\begin{bmatrix} u_0 \\ y_0 \end{bmatrix} = M \begin{bmatrix} u \\ y \end{bmatrix},$$

depend on the gain γ of system G and the elements of M . Let G be finite gain stable with gain γ . Then the system Σ_0 is

1. *Passive*, if M in (1) is chosen such that

$$\begin{aligned} m_{11} &= m_{21}, & m_{22} &= -m_{21}, \\ m_{11} &\geq m_{22}\gamma > 0. \end{aligned} \quad (2)$$

2. *Output Feedback Passive (OFP)* with OFP index $\rho_0 = \frac{1}{2} \left(\frac{m_{11}}{m_{21}} + \frac{m_{12}}{m_{22}} \right) > 0$, if

$$m_{21} \geq m_{22}\gamma > 0, \quad m_{11}m_{22} > m_{12}m_{21} > 0. \quad (3)$$

3. *Input Feedforward Passive (IFP)* with IFP index $\nu_0 = \frac{1}{2} \left(\frac{m_{21}}{m_{11}} + \frac{m_{22}}{m_{12}} \right) > 0$, if

$$m_{11} \geq m_{12}\gamma > 0, \quad m_{12}m_{21} > m_{11}m_{22} > 0. \quad (4)$$

4. *Passive with passivity levels* $\delta_0 = \frac{1}{2} \frac{m_{11}}{m_{21}} > 0$ and $\epsilon_0 = \frac{a}{2} \frac{m_{21}}{m_{11}} > 0$, if

$$m_{11} > 0, \quad m_{12} = 0, \quad m_{21} \geq \frac{m_{22}\gamma}{\sqrt{1-a}} > 0, \quad (5)$$

where $0 < a < 1$ is an arbitrary real number.

As an example, consider the plant $H = \frac{s+1}{s-1}$ which is unstable and nonpassive with OFP index $\rho = -1$. The controller $C = \frac{1}{0.2s+1}e^{-0.1s}$ is

nonpassive as well but finite-gain stable with $\gamma = 1$ and IFP index $\nu = -0.293$. The loop in this configuration is unstable. This situation could represent an actual physical system controlled by a human operator modeled as controller C . To guarantee stability, based on the above passivation method, one can set $m_{11} = 0.5, m_{12} = 0.4, m_{21} = 50$, and $m_{22} = 20$ to make the controller, C , IFP and stabilize the closed-loop system. In this example, the matrix M acts as an interface to passivate C and is placed between C and G .

Passivity and Passivity Indices in Switched and Hybrid Systems

Passivity has been extended to switched systems. There are several definitions of passivity for switched systems, and they can be classified into two main approaches. In the first approach, arbitrary switching is considered, and each subsystem is assumed passive. This is an important assumption that guarantees passivity for the case of no switching. Aside from that, different definitions impose different assumptions on the system regarding the energy added due to switching. In the second approach, nonpassive subsystems are allowed under certain conditions.

The definition of passivity through a common storage function, while useful, might not cover all practical considerations for a system. The passivity for each subsystem may have its own physical meaning and its own storage function. Here, we will focus on passivity and dissipativity of switched systems with multiple storage functions (sometimes referred to as *decomposable dissipativity*).

Consider the switched system of the form

$$\begin{aligned}\dot{x} &= f_\sigma(x, u_\sigma), \\ y &= h_\sigma(x)\end{aligned}\quad (6)$$

where σ is the switching signal taking values in

$$M = \{1, 2, \dots, s\}$$

which may depend on time or the state, or on both, or be governed by a higher-level hybrid feedback in the loop. The switching signal σ

generates a switching sequence

$$\Sigma = \{x_0; (i_0, t_0), (i_1, t_1), \dots, (i_n, t_n), \dots \mid i_n \in M, n \in \mathbb{N}\} \quad (7)$$

in which t_0 and x_0 are the initial time and state, respectively. This sequence implies that when $t \in [t_k, t_{k+1})$, then $\sigma(t) = i_k$, that is, the i_k th system is active, or the system is in *mode* i . It is assumed that the state of the switched system (6) does not jump at switching instances.

In Zhao and Hill (2008), passivity for switched systems is defined and used to prove stability results. Specifically, it was shown that passive systems are Lyapunov stable, that negative feedback induces asymptotic stability, and that output strictly passive (OSP) systems are asymptotically stable. System (6) is said to be dissipative under the switching law Σ if there exist positive-definite continuous functions $V_1(x), V_2(x), \dots, V_s(x)$, called storage functions, locally integrable functions $w_i^j(u_i, h_i)$, $1 \leq i \leq s$, called supply rates, and locally integrable functions $w_j^i(x, u_i, h_i, t)$, $1 \leq i, j \leq s, i \neq j$, called cross-supply rates, such that the following conditions hold

1. Each subsystem i is dissipative with respect to w_i^i while active, i.e.,

$$\begin{aligned}V_{i_k}(x(t)) - V_{i_k}(x(r)) \\ \leq \int_r^t w_{i_k}^{i_k}(u(\tau), h_{i_k}(x(\tau))) d\tau, \\ t_k \leq r \leq t < t_{k+1}\end{aligned}$$

2. Each subsystem j is dissipative with respect to w_j^j when the i th subsystem is active, i.e., for $k = 0, 1, 2, \dots, t_k \leq r \leq t < t_{k+1}$,

$$\begin{aligned}V_j(x(t)) - V_j(x(r)) \leq \int_r^t w_j^{i_k}(x(\tau), u_{i_k}(\tau), \\ h_{i_k}(x(\tau)), \tau) d\tau,\end{aligned}\quad (8)$$

for $j \neq i_k, k = 0, 1, 2, \dots, t_k \leq r \leq t < t_{k+1}$.

3. And for any i, j , there exist $u_i(t) = \alpha_i(x(t), t)$ and $\phi_j^i(t) \in \mathcal{L}_1^+[0, \infty)$, which may depend on u_i and the switching sequence, such that

$$f_i(0, \alpha_i(0, t)) \equiv 0, \quad \forall t \geq t_0 \quad (9)$$

$$w_i^j(u_i(t), h_i(x(t))) \leq 0 \quad \forall t \geq t_0 \quad (10)$$

and

$$w_j^j(x(t), u_i(t), h_i(x(t)), t) - \phi_j^i(t) \leq 0, \\ \forall j \neq i, \forall t \geq t_0.$$

In this framework, because all subsystems share the same state variables, the storage functions of subsystems are still changing on the time intervals even when they are inactive. The active subsystem drives the state which, in turn, causes the change of the storage functions of inactive subsystems. This “changing” energy of any inactive subsystem, though not necessarily real energy, is viewed as “exported energy” from the active subsystem and is characterized by cross-supply rates. Unlike the classical definition of dissipativity, this definition requires positive definite storage functions to induce stability and output stabilization. Here, passivity and passivity indices are defined from earlier definitions of IF-OFP systems by setting

$$w_j^j(x, u_j, h_j, t) = u_j^T h_j - \delta_j u_j^T u_j - \epsilon_j h_j^T h_j, \\ j = 1, 2, \dots, s$$

for some δ_j, ϵ_j .

It is straightforward to define constant passivity indices using the above definition of passivity; however, it is restrictive for switched systems to have constant indices regardless of the active subsystem. The alternative is to redefine the indices to be time varying. As the switched system changes the active subsystem, the value of the indices changes accordingly. In the case of a constant index, if the subsystems have OFP index set $\{\rho_i\}$ (IFP index set $\{v_i\}$), then the switched system is OFP with index $\rho = \min\{\rho_i\}$ (IFP with index $v = \min\{v_i\}$). Formally, if each

subsystem i has constant OFP index ρ_i (or IFP index v_i), then the overall switched system is OFP with index $\rho(t) = \rho_\sigma$ (IFP with index $v(t) = v_\sigma$), where σ denotes the index of the active subsystem (McCourt and Antsaklis 2010).

For more general switched systems in which some modes can be nonpassive, passivity can be achieved in the presence of nonpassive modes as well. Since the dynamics of some modes are not passive, by classical definitions, the system is not passive. However, if the nonpassive modes are active infrequently enough, the system can still be passive. In such a situation, a nonpassive system can be rendered locally passive using feedback control laws if and only if its zero dynamics are locally passive. This definition is consistent with the traditional definition of passivity in the sense that useful properties, such as stability and compositionality, are preserved.

The M-matrix method can also be generalized to switched controllers consisting of N nonpassive subsystems. In this case, a switched controller is placed in feedback configuration of a nonpassive, unstable plant, and the passivation matrix M is also time varying and switches among constant values whenever the controller switches. Due to the complexity of the switched system, it might be difficult to switch among different passivation matrices, so a single passivation matrix can be designed to compensate for the lack of passivity in the system. Placing the passivated switched controller in the negative feedback interconnection of a nonpassive and unstable plant can make the closed-loop system passive and stable.

Passivity Indices in Networked Control Systems

Networks are an essential part of CPS, making possible the integration of many distributed components. The elements in a CPS are usually spatially distributed and communicate over a wired or wireless link. The use of communication links in large-scale systems brings many advantages including ease of maintenance, flexibility, scalability, and lower costs. However, employing

shared multipurpose communication networks, as opposed to traditionally dedicated connections, brings out many challenges caused by packet dropouts, signal quantization, time delays, fading channels, and limited information transfer.

Delays are the most common effects of communication networks, and it is known that delay can disrupt passivity. A wave variable transformation can be employed to compensate for the effects of delays when interconnecting passive systems. With some modification, wave variable transformations are also applicable to the case of networked switched systems where two switched systems connected in negative feedback communicate over a network with time delays. The main idea in this transformation is to treat the delayed network as a two-port network. The two-port network being passive ensures the passivity of the whole interconnection. The interconnection, including the transformations, is depicted in Fig. 2. The wave variable transformation is given as

$$\begin{aligned} \begin{bmatrix} u_1 \\ \hat{v}_1 \end{bmatrix} &= \frac{1}{\sqrt{2b}} \begin{bmatrix} I & bI \\ -I & bI \end{bmatrix} \begin{bmatrix} y_{2d} \\ y_1 \end{bmatrix} \\ \begin{bmatrix} \hat{u}_2 \\ \hat{v}_2 \end{bmatrix} &= \frac{1}{\sqrt{2b}} \begin{bmatrix} I & bI \\ -I & bI \end{bmatrix} \begin{bmatrix} y_2 \\ y_{1d} \end{bmatrix} \end{aligned} \quad (11)$$

where

$$\hat{u}_2 = u_1(t - T_2) = u_2, \quad \hat{v}_1 = v_2(t - T_1) = v_1 \quad (12)$$

where the network delays T_1 and T_2 and the design parameter b are constant. For time-varying delays, the following modified transformation

$$\begin{aligned} \hat{u}_2 &= g_1(t)u_1(t - T_2(t)) = g_1(t)u_2(t) \\ \hat{v}_1 &= g_2(t)v_2(t - T_1(t)) = g_2(t)v_1(t) \end{aligned} \quad (13)$$

is used, where the design functions $g_1(t)$, $g_2(t)$ and delays $T_1(t)$, $T_2(t)$ satisfy

$$\begin{aligned} g_1^2(t) &\leq 1 - \frac{dT_2}{dt}, \quad g_2^2(t) \leq 1 - \frac{dT_1}{dt} \\ \frac{dT_1}{dt} &\leq 1, \quad \frac{dT_2}{dt} \leq 1 \end{aligned}$$

Similar transformations can be applied to the interconnection of two passive hybrid automata

Passivity and Passivity Indices for Switched and Cyber-physical Systems, Fig. 2 Two systems connected over a network with delays using wave variable transform

connected over a network with time-varying or constant delays to passivate, and under certain assumptions stabilize, the interconnection (Agarwal et al. 2016).

In the presence of packet dropouts, the networked control system is modeled as a discrete-time switched nonlinear system that switches between two modes: an uncontrolled mode in which the system evolves in open loop and a controlled mode in which a control input is applied to the system. If the ratio of the time steps for which the system evolves in open loop versus the time steps for which the system evolves in closed loop is bounded by a critical ratio, then the nonlinear system is locally passive.

Quantization is another widely seen phenomenon in digital controllers and communication channels. The control framework of Zhu et al. (2012) maintains passivity for switched and non-switched systems under quantization, based on the use of an input-output coordinate transformation to recover the passivity property.

Event-Triggered Networked Control Systems

Event-triggered control is an efficient network control method that limits the communication loads on the network and provides a balance between performance, communication

constraints, and control actions. In a typical event-triggered feedback framework, the information, whether it is a measurement or a control action, is transmitted only when necessary. Compared to time-driven control where a constant sampling period is applied to guarantee stability in the worst case scenario, the possibility of reducing the number of computations and thus of transmissions while guaranteeing desired levels of performance makes event-triggered control very appealing in networked control CPS. Passivity and passivity indices-based control combined with event-triggered networked control systems (NCS) provide a powerful tool for designing CPS.

When two systems are in feedback configuration with event-triggered communication in between, the passivity indices of the interconnection, as well as the finite gain $\mathcal{L}_2$ stability, relate to the passivity indices of each subsystem and the triggering condition. This relation is well documented in the literature (Yu and Antsaklis 2013). Based on this relation, the triggered control can be designed to achieve passive interconnections. This extends the compositionality properties of passivity to event-triggered systems.

Many of the challenges mentioned above for networked control systems that are not event triggered are also present in the event-triggered case as well. When network delays, quantization errors, and/or data loss are present in the event-triggered structure, passivity and passivity indices can be used to drive triggering conditions or to passivate and stabilize the system (Rahnama et al. 2018).

Further Readings

Basic definitions of dissipativity and passivity as well as their properties are given in Willems (1972). The discussion on passivity, particularly for nonlinear systems, is expanded in Hill and Moylan (1976) which lays the foundation for passivity indices. A review of applications of passivity in CPS is given in Antsaklis et al. (2013). The passivation method is based on Xia et al. (2014). Examples of applications of this method

to passivate a model of the human driver in a vehicle to guarantee passivity and performance exist in the literature as well (Xia et al. 2015).

Passivity indices of switched systems have various definitions. The definition we focused on here is from Zhao and Hill (2008). Passivity of switched systems with nonpassive subsystems is studied in Wang et al. (2014). The extensions to finite automata and hybrid systems can be found in Agarwal et al. (2017) and Haddad and Chellaboina (2001).

Several articles address passivity-based analysis and design of networked control system. For passivity of a NCS in the presence of packet dropouts, see Wang et al. (2015). The stability conditions for an event-triggered networked system based on the passivity properties of subsystems have been explored in Yu and Antsaklis (2011) and Zhu et al. (2017), with focus on passivity and passivation of event-triggered feedback interconnected systems of two input-feedforward, output-feedback passive systems. For a detailed illustration of the relationships among stability, robustness, and passivity levels of plant and controller, as well as an analysis of robustness against packet dropouts and passivity levels for the entire event-triggered networked control system, see Rahnama et al. (2018) and the references therein.

Passivity, Dissipativity, and Passivity Indices

Hasan Zakeri and Panos J. Antsaklis
Department of Electrical Engineering, University of Notre Dame, Notre Dame, IN, USA

Abstract

Passivity and dissipativity are energy-like concepts, widely used in control design, that capture the “energy” consumption of a dynamical system and therefore relate closely to the physical world. Passivity indices of a system are measures of its passivity margins and represent shortage and excess of passivity in a system. With the aid of passivity indices, one can measure how passive a system is, or how far from passivity it is. Passivity indices extend all the analysis and design methods based on passivity to nonpassive systems as well. One of the advantages of using passivity is its tight relationship to stability. Another is its compositionality, which, together with its generality, makes it possible to use passivity in a wide range of complex control systems. In the present entry, an overview of dissipativity and passivity is given. Passivity indices of a system and their relation to stability are defined, and methods to find the indices are presented.

Passivity and Passivity Indices

Consider a continuous-time dynamical system $\mathbf{H} : u \rightarrow y$, where $u \in \mathcal{U} \subseteq \mathbb{R}^m$ denotes the input and $y \in \mathcal{Y} \subseteq \mathbb{R}^p$ denotes the corresponding output. Let the system be described by the state space equations:

$$\begin{aligned}\dot{x} &= f(x, u) \\ y &= h(x, u),\end{aligned}\quad (1)$$

where $f(\cdot, \cdot)$ and $h(\cdot, \cdot)$ are Lipschitz mappings of proper dimensions, $x \in \mathbb{R}^n$, and assume the origin is an equilibrium point of the system; i.e., $f(0, 0) = 0$ and $h(0, 0) = 0$. The more general concept of dissipativity is defined first. The system (1) is called *dissipative with respect to the supply rate function* $w(u, y)$, if there exists a nonnegative real-valued scalar function $V(x)$, called the *storage function*, such that $V(0) = 0$ and for all $x_0 \in \mathcal{X}$, all $t_1 \geq t_0$, and all $u \in \mathbb{R}^m$

$$V(x(t_1)) \leq V(x(t_0)) + \int_{t_0}^{t_1} w(u(t), y(t)) dt. \quad (2)$$

where $x(t_0) = x_0$ and $x(t_1)$ is the state at t_1 resulting from initial condition x_0 and input function $u(\cdot)$ (Willems 1972). If $V(x)$ is differentiable, then condition (2) is equivalent to

$$\dot{V}(x) \triangleq \frac{\partial V}{\partial x} \cdot f(x, u) \leq w(u(t), y(t)). \quad (3)$$

If (2) is satisfied with

$$w(u, y) = y^T Q y + 2y^T S u + u^T R u \quad (4)$$

then the system is called QSR-dissipative. If (2) is satisfied with supply rate $w(u, y) = u^T y$, then the system is called passive. The storage function can be seen as a generalization of the energy stored in the system, and thus, the dissipation inequality (2) implies that the energy stored in the system at every moment, described by the storage function, is less than or equal to the energy supplied to the system plus the initially stored energy. The notion of energy here is a generalization of the physical energy, though, in many physical systems, the two can be the same.

A related definition of passivity that involves only input-output maps is given below. A system $\mathcal{H} : u \mapsto y$ is considered passive, if for every $u \in \mathcal{U}$, we have $\langle u, \mathcal{H}u \rangle \geq \beta$, for some $\beta \leq 0$ (which its value represents the initially stored energy). In the case of continuous-time

systems, the inner product $\langle \cdot, \cdot \rangle$ is defined as $\langle u(t), y(t) \rangle = \lim_{T \rightarrow \infty} \int_0^T u(t)^T y(t) dt$ (where the integral exists). For more details, as well as the existence of the inner product, see Hill and Moylan (1980) and van der Schaft (2017).

Passivity can be defined for a variety of systems, including linear, nonlinear, hybrid, and continuous-time or discrete-time systems. Passivity is particularly appealing in cyber-physical systems (CPS) design because it applies to heterogeneous systems and also it is preserved when systems are combined in parallel or feedback (Bao and Lee 2007). Passivity indices are introduced as measures of passivity, and they extend passivity-based tools to nonpassive systems as well.

System (1) is called *input feedforward passive (IFP)* if it is dissipative with respect to supply rate function $w(u, y) = u^T y - \nu u^T u$ for some $\nu \in \mathbb{R}$. The *input feedforward passivity index* for system (1) is the largest ν for which the system is IFP. If $\nu > 0$, the system is called input strictly passive (ISP). IFP index is also the largest gain that can be applied to the system via a negative feedforward interconnection such that the overall system is passive. For an input-output map $\mathcal{H}$, the IFP index is defined as the largest ν such that $\langle u, \mathcal{H}u \rangle \geq \beta + \nu \langle u, u \rangle$ for some $\beta \leq 0$.

System (1) is called *Output Feedback Passive (OFP)* if it is dissipative with respect to supply rate function $w(u, y) = u^T y - \rho y^T y$ for some $\rho \in \mathbb{R}$. The *output feedback passivity index* for system (1) is the largest ρ for which the system is OFP. If $\rho > 0$, the system is called output strictly passive (OSP). The OSP index is also the largest gain that can be applied to the system via a positive feedback interconnection such that the overall system is passive. For an input-output map $\mathcal{H}$, the OFP index is defined as the largest ρ such that $\langle u, \mathcal{H}u \rangle \geq \beta + \rho \langle \mathcal{H}u, \mathcal{H}u \rangle$ for $\beta \leq 0$.

System (1) is said to have IF-OFP levels (ε, δ) , if it is dissipative with respect to supply rate function $w(u, y) = (1 + \varepsilon\delta)u^T y - \delta y^T y - \varepsilon u^T u$ for some $\varepsilon, \delta \in \mathbb{R}$. Note that passivity indices ρ and ν are unique, but that is not the case for ε and δ . In an alternative definition, this system is said to have passivity levels

(ε', δ') , if it is dissipative with respect to supply rate function $w(u, y) = u^\top y - \delta' y^\top y - \varepsilon' u^\top u$ for some $\varepsilon', \delta' \in \mathbb{R}$. If $\varepsilon' > 0$ and $\delta' > 0$, the system is called very strictly passive (VSP).

It should be noted that although the emphasis here is on continuous-time systems, passivity and passivity indices are defined similarly for discrete-time systems.

Stability

Passivity and passivity indices have strong relations to stability. It is known that if the system (1) is passive with a positive definite storage function $V(x)$, then the autonomous system (with $u = 0$) is Lyapunov stable. Output strictly passive systems are $\mathcal{L}_2$ stable. Moreover, if system G is strictly passive with output passivity index ρ , then G is finite-gain $\mathcal{L}_2$ stable with gain $\gamma \leq \frac{1}{\rho}$.

Consider the feedback interconnection of Fig. 1, and suppose that each feedback component G_i has passivity levels $(\varepsilon'_i, \delta'_i)$. Then, the closed-loop map is finite gain $\mathcal{L}_2$ stable if $\varepsilon'_1 + \delta'_2 > 0$ and $\varepsilon'_2 + \delta'_1 > 0$. If each system has IF-OSP indices $(\varepsilon_i, \delta_i)$, then the interconnection is $\mathcal{L}_2$ stable if the following matrix is positive definite:

$$A = \begin{bmatrix} (\delta_1 + \varepsilon_2)I & \frac{1}{2}(\delta_1\varepsilon_1 - \delta_2\varepsilon_2)I \\ \frac{1}{2}(\delta_1\varepsilon_1 - \delta_2\varepsilon_2)I & (\delta_2 + \varepsilon_1)I \end{bmatrix} > 0 \quad (5)$$

Passivity in Linear Systems

In linear time-invariant (LTI) systems, there are strong relations among passivity and passivity indices, positive real and strictly positive

real systems, and the Kalman-Yakubovich-Popov lemma. A continuous-time LTI system, represented by an $m \times m$ rational and proper transfer function matrix $H(s)$, is positive real (PR) if the following conditions are satisfied:

- (i) All elements of $H(s)$ are analytic in $\text{Re}[s] > 0$.
- (ii) $H(s)$ is real for all real positive values of s .
- (iii) $H^\top(s^*) + H(s) \geq 0$ for $\text{Re}[s] > 0$, where s^* is the complex conjugate of s .

Furthermore, $H(s)$ is strictly positive real (SPR) if $\exists \sigma > 0$ such that $H(s - \sigma)$ is positive real. Finally, $H(s)$ is strongly positive real if $H(s)$ is SPR and $D + D^\top > 0$ where $D := \lim_{s \rightarrow \infty} H(s)$.

The definition of PR implies that the poles of $H(s)$ are in the closed left-half plane; therefore any minimal realization of $H(s)$ is Lyapunov stable. Strictly positive real implies that the poles of $H(s)$ are in the open left-half plane; therefore the system is $\mathcal{L}_2$ stable with an asymptotically stable minimal realization. Positive realness and strictly positive realness can be verified directly in the frequency domain. For LTI systems, the property of passivity is equivalent to the property of positive realness. Under mild technical assumptions, these systems are Lyapunov stable. For LTI systems, strict passivity is equivalent to strict positive realness. For asymptotically stable systems, strongly positive real is ISP. While OSP systems are passive and $\mathcal{L}_2$ stable, it should be noted that this relationship is sufficient only: systems that are passive and $\mathcal{L}_2$ stable are not necessarily OSP (see Kottenstette et al. 2014, Theorem 8 for constructive examples of such systems). It can also be stated that if a minimal realization of a transfer function is VSP, then the transfer function is strongly positive real.

Passivity, Dissipativity, and Passivity Indices,

Fig. 1 The general feedback interconnection of two dynamical systems G_1 and G_2

Computation of Passivity Indices

The use of linear matrix inequalities (LMIs) in passivity theory comes from earlier work on the positive real lemma, also known as the KYP (Kalman, Yakubovich, and Popov) Lemma. A linear time-invariant system is passive if and only if it is passive with a quadratic energy storage function (Khalil 2002). Therefore, a linear system described by

$$\begin{aligned}\dot{x} &= Ax + Bu, \\ y &= Cx + Du\end{aligned}\quad (6)$$

is passive if and only if there exists a positive-definite matrix P such that

$$\begin{aligned}\max \quad & \rho \\ \text{s.t.} \quad & P > 0, \\ & \begin{bmatrix} A^\top P + PA + \rho C^\top C & PB - 0.5C^\top + \rho C^\top D \\ B^\top P - 0.5C + \rho D^\top C & PB - 0.5C^\top + \rho C^\top D + \rho D^\top D - 0.5(D + D^\top) \end{bmatrix} \leq 0.\end{aligned}\quad (9)$$

The passivity indices for a linear system can also be found in the frequency domain. The IFP index for a stable linear system $G(s)$ can be computed as

$$\nu = \frac{1}{2} \min_{\omega \in \mathbb{R}} \underline{\lambda}(G(j\omega) + G^*(j\omega)), \quad (10)$$

where $\underline{\lambda}$ denotes the minimum eigenvalue. If the system $G(s)$ is minimum phase, then its OFP index is

$$\rho = \frac{1}{2} \min_{\omega \in \mathbb{R}} \underline{\lambda}(G^{-1}(j\omega) + [G^{-1}(j\omega)]^*), \quad (11)$$

where $G^{-1}(s)$ denotes the inverse of system $G(s)$.

The transfer function $G(s)$ may be rational or irrational. In the case of a single-input single-output (SISO) system, we can test the passivity of $G(s)$ using the Nyquist plot. If the Nyquist plot of $G(s)$ is in the closed right-hand half of the complex plane, then the system is passive; otherwise, the system is not passive. Similarly, IFP index ν is the abscissa of the leftmost point

$$\begin{bmatrix} A^\top P + PA & PB - C^\top \\ B^\top P - C & -D - D^\top \end{bmatrix} \leq 0. \quad (7)$$

Passivity indices can be found using similar LMIs. The IFP index ν is the solution to the following optimization problem

$$\begin{aligned}\max \quad & \nu \\ \text{s.t.} \quad & P > 0, \\ & \begin{bmatrix} A^\top P + PA & PB - 0.5C^\top \\ B^\top P - 0.5C & -0.5(D + D^\top) - \nu I \end{bmatrix} \leq 0.\end{aligned}\quad (8)$$

Similarly, OFP index ρ is solution to the following optimization

on the Nyquist diagram of $G(s)$ and the OFP index ρ is the abscissa of the leftmost point on the Nyquist diagram of $G^{-1}(s)$.

Defining the OFP index as mentioned above imposes a minimum phase condition on the system. Now consider a SISO system with transfer function $H(s)$ and corresponding frequency response $H(j\omega)$. If H is OSP, then its OFP index ρ satisfies the following inequality

$$0 < \rho < \inf_{\omega \in [0, \infty)} \frac{\Re[H(j\omega)]}{\Re[H(j\omega)^2 + \Im[H(j\omega)]^2]}. \quad (12)$$

There are sum of squares (SOS) methods to determine the passivity indices of nonlinear systems (Zakeri and Antsaklis 2019b). There are also relations between passivity indices of a nonlinear system and its approximations, e.g., linearization (Xia et al. 2015). The indices for switched and networked control systems are discussed in a companion entry titled “► [Passivity and Passivity Indices for Switched and Cyber-Physical Systems](#)”.

Further Readings

Basic definitions of dissipativity and passivity as well as their properties are given in Willems (1972). The discussion on passivity, particularly for nonlinear systems, is expanded in Hill and Moylan (1976) laying the foundation for passivity indices. For more details on the relation of passivity and passivity indices with stability, see Khalil (2002) and Haddad and Chellaboina (2008). A detailed discussion on the relation of passivity, positive realness, and dissipativity is presented in Kottenstette et al. (2014). Data-driven methods for approximating passivity indices have also been introduced, as well as application of such approximations in fault and attack mitigation. See Romer et al. (2018) for an offline iterative method and Zakeri and Antsaklis (2019a) for online estimation and adaptive control reconfiguration method. A review of applications of passivity in CPS is given in Antsaklis et al. (2013) and Zakeri and Antsaklis (2019c).

Abstract

Stabilization of physical systems by shaping their energy function is a well-established technique whose roots date back to the

work of Lagrange and Legendre. Potential energy shaping for fully actuated mechanical systems was first introduced in Takegaki and Arimoto (Trans ASME J Dyn Syst Meas Control 12:119–125, 1981) more than 30 years ago. In Ortega and Spong (Automatica 25(6):877–888, 1989) it was proved that passivity was the key property underlying the stabilization mechanism of these designs, and the, now widely popular, term of passivity-based control was coined. In this chapter we summarize the basic principles and some of the main developments of this controller design technique.

Keywords

Stabilization · Lyapunov function · Energy shaping · Storage function · Dissipation

Introduction

Energy is one of the fundamental concepts in science and engineering practice, where it is common to view dynamical systems as energy transformation devices. This perspective is particularly useful in studying *complex nonlinear* systems by decomposing them into simpler subsystems which, upon interconnection, add up their energies to determine the full system's behavior. The action of a controller may be also understood in energy terms as another dynamical system – typically implemented in a computer – interconnected with the process to modify its behavior. Then, the control problem can be recast as finding a dynamical system and an interconnection pattern such that the overall energy and dissipation functions take the desired form. This “energy-shaping plus dissipation” approach is the essence of the controller design technique – known as passivity-based control (PBC) – that is reviewed in this chapter.

We consider dynamical systems represented as multiports with port variables $(u, y) \in \mathbb{R}^m \times \mathbb{R}^m$. In physical systems, the port variables are conjugated, in the sense that their product represents power. In this case, passivity captures the

well-known property that the energy that can be extracted from the system is bounded, that is, there exists $\beta \in \mathbb{R}$ such that

$$-\int_0^t u^\top(s)y(s)ds \leq \beta.$$

Motivated by practical applications, we assume that the system admits a state-space representation given in the input-state-output form

$$\begin{aligned}\dot{x} &= f(x) + g(x)u \\ y &= h(x),\end{aligned}\tag{1}$$

where $x \in \mathbb{R}^n$ is the state, and we view the system as a mapping $\Sigma : u \mapsto y$. It is said to be passive if there exists a function $H(x) \geq 0$ – called the storage function – such that the power-balance inequality

$$\dot{H} \leq u^\top y\tag{2}$$

holds. In physical systems a reasonable candidate for $H(x)$ is the energy of its energy-storing elements, e.g., capacitors, inductors, dampers, and masses.

An algebraic description of passive systems of the form (1) is given in Hill and Moylan (1980), where it is shown that a necessary condition for a system to be passive is that

$$h(x) = g^\top(x)\nabla H(x).\tag{3}$$

A geometric characterization of systems that can be rendered passive via state feedback is reported in Byrnes et al. (1991).

The objective of PBC, in the simplest static state-feedback formulation, is to find a function $\hat{u} : \mathbb{R}^n \rightarrow \mathbb{R}^m$ such that the system (1) in closed-loop with the control law $u = \hat{u}(x) + v$ satisfies the new power balance inequality

$$\dot{H}_d \leq v^\top y_d,\tag{4}$$

where $(v, y_d) \in \mathbb{R}^m \times \mathbb{R}^m$ are the new port variables and $H_d(x) \geq 0$ is the *desired* storage function. This first step of PBC is known as *energy shaping*. The second step in PBC, known

as *damping injection*, is to set $v = -K_{\text{DI}}y_d$, with $K_{\text{DI}} > 0$, then $\dot{H}_d \leq -y_d^\top K_{\text{DI}}y_d$.

Chapter notation All mappings are supposed smooth. Consider the mapping $F : \mathbb{R}^n \rightarrow \mathbb{R}^m$. We define the ij -th element of the $n \times m$ matrix $\nabla_x F(x)$ as $(\nabla_x F)_{ij} := \frac{\partial F_j}{\partial x_i}$. When clear from the context, the subindex in ∇ is omitted. For any F and the distinguished element $x^* \in \mathbb{R}^n$, we define the constant matrix $F^* := F(x^*)$. Consider the case $n \geq m$ and $\text{rank}\{F\} = m$. Then, the pseudoinverse of F is denoted by $F^\dagger$, that is, $F^\dagger := (F^\top F)^{-1}F^\top$ and $F^\dagger F = I_m$. The left annihilator of F is represented as $F^\perp$, where $\text{rank}\{F^\perp\} = n - m$, and $F^\perp F = \mathbf{0}_{(n-m) \times m}$.

Equilibrium Stabilization via PBC

PBC is often used for Lyapunov stabilization of equilibria. For this task, the key observation is that if $H_d(x)$ verifies

$$x^* = \arg \min H_d(x), \quad (5)$$

where $f(x^*) + g(x^*)\hat{u}(x^*) = \mathbf{0}_n$, then x^* is a *stable* equilibrium of the system in closed-loop with $u = \hat{u}(x)$, with Lyapunov function $H_d(x)$. Moreover, adding the *damping injection* step, the equilibrium x^* will be *asymptotically* stable if y_d is a detectable output for the closed-loop system – see van der Schaft (2016, Corollary 4.2.2).

Energy-Balancing PBC and the Dissipation Obstacle

The most natural way to carry out the energy shaping is to fix $y_d = y$, to look for a function $H_a : \mathbb{R}^n \rightarrow \mathbb{R}_{\geq 0}$, solution of the equation

$$\dot{H}_a = -h^\top(x)\hat{u}(x), \quad (6)$$

and to define $H_d(x) = H(x) + H_a(x)$. This variation of PBC is called energy balancing (EB) (Ortega et al. 2001), because $H_d(x)$ consists of the sum of the systems energy and the energy provided by the controller, e.g., $y^\top u$. In spite of

this appealing interpretation, EB-PBC has two serious shortcomings. On one hand, the Eq. (6), which is a partial differential equation (PDE) of the form

$$[\nabla H_a(x)]^\top [f(x) + g(x)\hat{u}(x)] = -h^\top(x)\hat{u}(x),$$

is not amenable for an easy interpretation – because of its explicit dependence on the feedback signal that we are looking for. On the other hand, it is applicable only to systems that are not constrained by the *dissipation obstacle*, that is, systems where dissipation is absent in steady state and can, therefore, be stabilized extracting a finite amount of energy from the controller. Indeed, it is clear that a necessary condition for the existence of a solution of (6) is that $h^\top(x^*)\hat{u}(x^*) = 0$.

The main domain of application of EB-PBC is in regulation of the position $q \in \mathbb{R}^\ell$ of mechanical systems, where $\ell = \frac{n}{2}$. In this case, the dissipation obstacle is conspicuous by its absence because the passive output is velocity $\dot{q}$. Moreover, since in this case we are only interested in adding a new function $V_a(q)$ to the potential energy function, the PDE to be solved reduces to $G^\perp(q)\nabla V_a(q) = \mathbf{0}_{\ell-m}$, where the input matrix is of the form $g(q, \dot{q}) = [\mathbf{0}_{\ell \times m}^\top G^\top(q)]^\top$. In the particular case of fully actuated mechanical systems, it is possible to remove the open-loop potential energy and assign a desired one. This idea was introduced in the pioneering work Takegaki and Arimoto (1981).

Generating Alternative Passive Outputs

One way to overcome the dissipation obstacle is to enforce the power balance inequality (4) with outputs $y_d \neq y$. To achieve this end, it is convenient to restrict our attention to *port-Hamiltonian* (pH) systems, that is systems where

$$f(x) = [\mathcal{J}(x) - \mathcal{R}(x)]\nabla H(x), \quad (7)$$

where $\mathcal{J}(x) = \mathcal{J}^\top(x)$ is the interconnection matrix and $\mathcal{R}(x) \geq 0$ is the dissipation matrix. See van der Schaft (2016) for an extensive discussion, and well-founded practical motivation,

of this class of systems. The following result, which characterizes all passive outputs of the pH system with storage function $H(x)$, was recently established in Zhang et al. (2018).

Lemma 1 Consider the pH system (1) and (7). Introduce the factorization $\mathcal{R}(x) = \phi^\top(x)\phi(x)$, where $\phi(x) \in \mathbb{R}^{q \times n}$, with $q \geq \text{rank} \{\mathcal{R}(x)\}$ and define $y_d := h(x) + j(x)u$. The following statements are equivalent.

- (S1) The mapping $u \mapsto y_d$ is passive with storage function $H(x)$.
- (S2) The mappings $h(x)$ and $j(x)$ can be expressed as

$$\begin{aligned} h(x) &= [g(x) + 2\phi^\top(x)w(x)]^\top \nabla H(x) \\ j(x) &= w^\top(x)w(x) + D(x), \end{aligned}$$

for some mappings $w(x) \in \mathbb{R}^{q \times m}$ and $D(x) \in \mathbb{R}^{m \times m}$, with $D(x) = -D^\top(x)$.

One particularly attractive output that allows us to overcome the dissipation obstacle is the so-called *power-shaping* output. With a suitable selection of the mappings $w(x)$ and $D(x)$ in Proposition 1, it is possible to generate the output

$$\begin{aligned} y_d &= -g^\top(x)[\mathcal{J}(x) - \mathcal{R}(x)]^{-\top} \{[\mathcal{J}(x) \\ &\quad - \mathcal{R}(x)]\nabla H(x) + g(x)u\}, \end{aligned}$$

where, for ease of presentation, it is assumed that the matrix $\mathcal{J}(x) - \mathcal{R}(x)$ is full rank. Since $y_d = \mathbf{0}_m$ at the equilibrium, it is clear that the dissipation obstacle is absent for the system $u \mapsto y_d$.

Interconnection and Damping Assignment (IDA)-PBC

A variation of PBC that has been very successful in many practical applications is IDA-PBC. The main result of IDA-PBC is the following proposition, whose proof may be found in Ortega et al. (2002a).

Proposition 1 Consider the system (1). Assume there are matrices $\mathcal{J}_d(x) = -\mathcal{J}_d^\top(x)$, $\mathcal{R}_d(x) = \mathcal{R}_d^\top(x) \geq 0$, and a function $H_d(x)$, that verify the

matching equation

$$g^\perp(x)f(x) = g^\perp(x)[\mathcal{J}_d(x) - \mathcal{R}_d(x)]\nabla H_d. \quad (8)$$

Then, the closed-loop system with $u = \hat{u}(x)$, where

$$\hat{u}(x) := g^\dagger(x)\{[\mathcal{J}_d(x) - \mathcal{R}_d(x)]\nabla H_d - f(x)\},$$

takes the pH form $\dot{x} = [\mathcal{J}_d(x) - \mathcal{R}_d(x)]\nabla H_d$. Moreover, if $x^* \in \{x \mid g^\perp(x)f(x) = \mathbf{0}_{n-m}\}$ and (5) holds, it is a stable equilibrium.

Conversely, if there exists $\hat{u}(x)$ that globally asymptotically stabilizes (1), then there exist $\mathcal{J}_d(x)$, $\mathcal{R}_d(x)$, and $H_d(x)$ which satisfy (8).

The key step in the IDA-PBC design is, of course, the solution of (8), and there are several approaches to carry out this task. In the non-parameterized IDA-PBC, we fix $\mathcal{J}_d(x)$ and $\mathcal{R}_d(x)$, and (8) becomes a PDE for $H_d(x)$. In algebraic IDA-PBC (Fujimoto and Sugie 2001), we fix $H_d(x)$, and (8) becomes an algebraic equation in $\mathcal{J}_d(x)$ and $\mathcal{R}_d(x)$. In some applications, it is of interest to fix the structure of the desired energy function, for instance, for mechanical systems, it is reasonable to propose

$$H_d(q, p) = \frac{1}{2}p^\top M_d^{-1}(q)p + V_d(q);$$

whence (8) becomes a PDE in the desired inertia matrix $M_d(q)$ and the desired potential energy function $V_d(q)$ – this approach is called parameterized IDA-PBC (Ortega et al. 2002b), with a Lagrangian version given in Bloch et al. (2000). Clearly, fixing this structure imposes some particular constraints on $\mathcal{J}_d(x)$ and $\mathcal{R}_d(x)$. Finally, for nonlinear systems of the form $\dot{x} = f(x, u)$, Poincaré's Lemma states that a necessary and sufficient condition for the solution of the matching equation

$$\nabla H_d(x) = [\mathcal{J}_d(x) - \mathcal{R}_d(x)]^{-1} f(x, \hat{u}(x))$$

is that the right-hand side is a gradient vector field. Fixing $\mathcal{J}_d(x)$ and $\mathcal{R}_d(x)$, this condition translates into a PDE directly for $\hat{u}(x)$.

Proportional-Integral-Derivative (PID)-PBC

PID controllers overwhelmingly dominate engineering applications where the control objective is to regulate some measurable signal y around a constant desired value y^* . Commissioning of PIDs reduces to the suitable selection of the controller gains, which is a difficult task for wide-ranging operating systems, where the validity of a linearized approximation is limited, compromising the stability of the closed-loop. Although gain scheduling, auto-tuning, and adaptation provide some help to overcome this problem, they suffer from well-documented drawbacks. In contrast to this scenario, in PID-PBC, where the PID is wrapped around a passive output, the gain tuning step is trivialized. Indeed, PIDs

$$\begin{aligned}\dot{x}_c &= y \\ u &= -K_P y - K_I x_c - K_D \dot{y},\end{aligned}\quad (9)$$

define, (output-strictly) passive maps $u \mapsto -y$, with storage function $\frac{1}{2}y^\top K_D y + \frac{1}{2}x_c^\top K_I x_c$, for all positive gains. Therefore, convergence of the output to zero and $\mathcal{L}_2$ -stability of the closed-loop system is always guaranteed – and the designers task is only to select the gains that ensure best transient performance.

Shifted Passivity

It is often the case that the reference output $y^* \neq 0$, that suggests to wrap the PID around the error signal $y - y^*$. Unfortunately, for general nonlinear systems, passivity of the mapping $u \mapsto y$ does not imply passivity of $(u - u^*) \mapsto (y - y^*)$ – a property called “shifted passivity” in van der Schaft (2016). The strongest conditions under which the implication holds for pH systems have been reported in Monshizadeh et al. (2019) where, in particular, the following easily verifiable necessary and sufficient condition is given for systems with quadratic nonlinearities.

Lemma 2 Consider the pH system (1) and (7) with g and $\mathcal{R}$ constants,

$$H(x) = \frac{1}{2}x^\top Qx, \quad Q > 0, \quad \mathcal{J}(x) = \mathcal{J}_0 + \sum_{i=1}^n \mathcal{J}_i x_i.$$

Fix

$$\begin{aligned}(x^*, u^*) &\in \{(x, u) \in \mathbb{R}^n \times \mathbb{R}^m \mid \\ &[\mathcal{J}(x) - \mathcal{R}]\nabla H(x) + gu = \mathbf{0}_n\}.\end{aligned}$$

The system satisfies $\dot{\mathcal{H}} \leq (y - y^*)^\top (u - u^*)$, with $\mathcal{H}(x) := \frac{1}{2}(x - x^*)^\top Q(x - x^*)$, if and only if

$$\begin{aligned}&\left(\sum_{i=1}^n \mathcal{J}_i - \mathcal{R}\right)Qx^*e_i^\top Q^{-1} \\ &+ \left[\left(\sum_{i=1}^n \mathcal{J}_i - \mathcal{R}\right)Qx^*e_i^\top Q^{-1}\right]^\top \\ &- 2\mathcal{R} \leq 0,\end{aligned}$$

where $e_i \in \mathbb{R}$ is the i -th element of the orthogonal basis.

Leveraging Lemma 2, we can confidently wrap a PID around the shifted output $y - y^*$. One important observation is that, in the implementation of the PID, there is no need to know u^* . Indeed, by shifting the storage function, we can establish passivity of the map $u \mapsto y - y^*$.

Lyapunov Stabilization via PID-PBC

Another scenario of practical interest is when the control objective cannot be captured by the behavior of an output signal, for instance, when it is desired to drive the full system *state* to a desired equilibrium x^* . To treat this case, it is necessary to create a Lyapunov function for the closed-loop system, an approach taken for pH systems in Zhang et al. (2018). The main difficulty in this case is how to ensure the positivity (with respect to x^*) of the function. Indeed, although for a passive system (1) in closed-loop with a PID (9), we can prove that the function

$$U(x, x_c) := H(x) + \frac{1}{2}h^\top(x)K_D h(x) + \frac{1}{2}x_c^\top K_I x_c$$

satisfies $\dot{U} \leq -y^\top K_P y$ and the function $U(x, x_c)$ is not positive definite – therefore, it does not qualify as a Lyapunov function. One way to overcome this obstacle is to find a mapping

$\gamma(x) \in \mathbb{R}^m$ such that the multilevel set

$$\Gamma := \{(x, x_c) \in \mathbb{R}^n \times \mathbb{R}^m \mid x_c = \gamma(x) + \kappa, \kappa \in \mathbb{R}^m\} \quad (10)$$

is *invariant* and the function

$$H_d(x) := H(x) + U(x, \gamma(x) + \kappa) \quad (11)$$

verifies (5), for some $\kappa \in \mathbb{R}^m$. As expected, this involves the solution of a PDE, as shown below.

Lemma 3 Consider the pH system (1), (7), and $\dot{x}_c = y_d$, with y_d defined in Lemma 1. Assume there exists mappings $w(x)$ and $D(x)$ such that the PDE

$$\begin{aligned} & \begin{bmatrix} [\nabla H(x)]^\top F^\top(x) \\ g^\top(x) \end{bmatrix} \\ \nabla \gamma(x) &= \begin{bmatrix} [\nabla H(x)]^\top [g(x) + 2\phi^\top(x)w(x)] \\ w^\top(x)w(x) - D(x) \end{bmatrix} \end{aligned}$$

admits a solution $\gamma(x) \in \mathbb{R}^m$. Then, the set Γ , given in (10), is *invariant*.

Combining Lemmata 1 and 3, we can complete the design of the PID-PBC as follows.

Proposition 2 Consider the pH system (1) and (7) in closed-loop with the PID-PBC

$$u = -K_P y_d - K_I [\gamma(x) + \kappa] - K_D \dot{y}_d.$$

where $\kappa = -(\gamma^* + K_I^{-1}u^*)$ and y_d is defined as in Lemmata 1 and 3. Assume that $H_d(x)$, given in (11), verifies (5). Then, the closed-loop system has a stable equilibrium at x^* with Lyapunov function (11). Moreover, the equilibrium is asymptotically stable if y_d is a detectable output for the closed-loop system.

Standard PBC of Euler-Lagrange (EL) Systems

Another variation of PBC, particularly suitable for systems described by Euler-Lagrange equations of motion is the so-called standard PBC, that was thoroughly explored in Ortega et al. (2013).

Mathematical Model and Passivity Property

In this case we deal with dynamical systems with ℓ degrees-of-freedom, generalized coordinates $q \in \mathbb{R}^\ell$, and external forces $Q \in \mathbb{R}^\ell$, which are described by the EL equations

$$\frac{d}{dt} [\nabla_{\dot{q}} \mathcal{L}(q, \dot{q})] - \nabla_q \mathcal{L}(q, \dot{q}) = F, \quad (12)$$

where $\mathcal{L}(q, \dot{q}) := T(q, \dot{q}) - V(q)$ is the Lagrangian function, $T(q, \dot{q}) = \frac{1}{2} \dot{q}^\top M(q) \dot{q}$, is the kinetic (co-energy) function, with $M(q) > 0$ the generalized inertia matrix, and $V(q)$ is the potential energy function. The vector F is the external forces that take the form $F = -\nabla \mathcal{F}(\dot{q}) + G(q)u$, where $u \in \mathbb{R}^m$, $m \leq \ell$ are the control and dissipation forces and $\mathcal{F}(\dot{q})$ is the Rayleigh dissipation function verifying $\dot{q}^\top \nabla \mathcal{F}(\dot{q}) \geq 0$.

It is well-known that the EL system (12) defines a passive operator $u \mapsto G^\top(q) \dot{q}$ with storage function, the system's total energy $H(q, \dot{q}) = T(q, \dot{q}) + V(q)$, see Proposition 2.5 in Ortega et al. (2013). Moreover, it is possible to prove a “stronger” property. Namely, if we define an $\ell \times \ell$ matrix $C(q, \dot{q})$ – called in the robotics literature the “Coriolis and centrifugal forces” matrix – with ik -th entry

$$C_{ik}(q, \dot{q}) = \sum_j^\ell c_{ijk}(q) \dot{q}_j.$$

where

$$\begin{aligned} c_{ijk}(q) &:= \frac{1}{2} [\nabla_{q_j} m_{ik}(q) + \nabla_{q_i} m_{jk}(q) \\ &\quad - \nabla_{q_k} m_{ij}(q)] \end{aligned}$$

are the Christoffel symbols of the first kind (Ortega and Spong 1989). Then, the EL system becomes

$$M(q) \ddot{q} + C(q, \dot{q}) \dot{q} + \nabla \mathcal{F}(\dot{q}) + \nabla V(q) = G(q, \dot{q})u, \quad (13)$$

where

$$\begin{aligned} \dot{M}(q) &= C(q, \dot{q}) + C^\top(q, \dot{q}) \\ \Leftrightarrow z^\top [\dot{M}(q) - 2C(q, \dot{q})]z &= 0, \\ \forall z &\in \mathbb{R}^\ell. \end{aligned} \quad (14)$$

Standard PBC

The skew-symmetry property (14), which identifies the work-less forces, is the key component of standard PBC. The main result, for regulation of q , of this technique is given as follows.

Proposition 3 *Consider the EL system (13) verifying (14). Fix the desired position $q^* \in \{q \in \mathbb{R}^\ell \mid G^\perp(q) \nabla V(q) = \mathbf{0}_{\ell-m}\}$. Assume it is possible to find signals $q_d \in \mathbb{R}^\ell$ satisfying the equation*

$$G^\perp(q) [M(q)\ddot{q}_d + C(q, \dot{q})\dot{q}_d + \nabla \mathcal{F}(\dot{q}) + \nabla V(q) - K_D \dot{\tilde{q}} - K_P \tilde{q}] = \mathbf{0}_{\ell-m},$$

where $K_D, K_P > 0$, $\tilde{q} := q - q_d$, and that for the system

$$M(q)\ddot{\tilde{q}} + C(q, \dot{q})\dot{\tilde{q}} + K_D \dot{\tilde{q}} + K_P \tilde{q} = \mathbf{0}_\ell, \quad (15)$$

it is possible to prove that

$$\tilde{q}, \dot{\tilde{q}} \in \mathcal{L}_\infty, \quad \dot{\tilde{q}}(t) \rightarrow \mathbf{0}_\ell \Rightarrow q, \dot{q} \in \mathcal{L}_\infty, \quad q(t) \rightarrow q^*. \quad (16)$$

Under these conditions, the system (13) in closed-loop with the control

$$u = G^\dagger(q) [M(q)\ddot{q}_d + C(q, \dot{q})\dot{q}_d + \nabla \mathcal{F}(\dot{q}) + \nabla V(q) - K_D \dot{\tilde{q}} - K_P \tilde{q}]$$

ensures $q(t) \rightarrow q^*$ with all internal signals bounded.

The gist of the proof is the observation that the error system is given by (15) and that for this system we have the following

$$\begin{aligned} H_d(\tilde{q}) &:= \frac{1}{2} \dot{\tilde{q}}^\top D \dot{\tilde{q}} + \tilde{q}^\top K_P \tilde{q} \Rightarrow \dot{H}_d \\ &= -\dot{\tilde{q}}^\top K_v \dot{\tilde{q}}. \end{aligned}$$

Then, some easy signal chasing and the implication (16) allow us to complete the proof.

The procedure described above is an extension of the well-known controller for fully actuated robot manipulators of Slotine and Li (1988). In that case, $G(q) = I_\ell$ and stabilization (or tracking) of q^* are ensured by selecting

$$q_d := q^* - \Lambda(q - q^*), \quad \Lambda > 0.$$

For underactuated systems, it is not possible to fix all signals q_d to desired values; whence some of them are defined as states of the controller dynamics. In Ortega et al. (2013) the method is applied to a large variety of physical systems, including underactuated mechanical systems, electrical motors, power converters, and levitated systems. Particularly noteworthy is the proof that applying standard PBC to induction motors yields a controller that contains, as a particular case, the industry standard field-oriented control. One major drawback of the method is that the calculation of the controller involves an implicit inversion of the system dynamics; hence its application is restricted to minimum phase systems. This limitation is conspicuous by its absence in IDA-PBC.

Summary and Future Directions

In physical systems, the concepts of energy and dissipation are well defined. Therefore, passivity theory and PBC techniques emerge as natural options to analyze and control, respectively, this kind of systems. However, the range of applicability of PBC is not constrained to physical systems; as a matter of fact, the possibility of decomposing complex nonlinear systems into simpler subsystems makes this approach appealing to tackle down modern problems in control, such as stabilization of biological systems or smart grids.

Pattern Formation in Spin Ensembles

Jr-Shin Li

Department of Electrical and Systems Engineering, Washington University in St. Louis, St. Louis, MO, USA

Abstract

Many applications in quantum science and technology involve controlling the collective

behavior or engineering excitation profiles of a large inhomogeneous ensemble. Developing electromagnetic pulses to achieve these exercises has been a long-standing challenging problem in the field of quantum control. Here, we view this problem through the lens of ensemble control providing some background material on the relevant developments and discussing some specific problem areas where these ideas play a role.

Keywords

Ensemble control · Spin ensembles · Pulse design · Non-harmonic Fourier expansion · Alternating minimization · Coherence transfer

Introduction

The capability to precisely manipulate the time evolution of a quantum ensemble constitutes a significant step toward advancing quantum science and engineering. State-of-the-art quantum technologies can be used to trap and experiment with individual atoms (quantum optics), image brains (magnetic resonance imaging (MRI)), and generate structural and dynamical information of biological macromolecules (nuclear magnetic resonance (NMR) spectroscopy). Many of these applications involve manipulating collective behavior, more specifically engineering excitation patterns, in a large quantum ensemble. A canonical way to enable these applications is through the design and application of time-varying electromagnetic pulses (controls) that are broadcast to the systems at the population level, and inhomogeneities across the entire population of quantum systems, let alone its tremendous scale, form a bottleneck for control-theoretic analysis and design.

From early work using physical intuition (Hahn 1950) to modern methods like composite pulses (Levitt 1986) and gradient flow-based numerical optimization (Khaneja et al. 2005), extensive pulse design techniques have been proposed over the past decades (Bernstein et al.

2004), and the process of innovation is ceaseless. Recent years have witnessed numerous attempts to tackle pulse design problems from a control theory point of view, and these methods have demonstrated promises to establish a systematic and justifiable framework for pulse design (Khaneja et al. 2005; Khaneja et al. 2003; Warren et al. 1993; Li et al. 2011). In this entry, we will view the problem of pulse design through the lens of ensemble control and discuss some specific problem areas where the ensemble control ideas play a critical role.

Control of Spin Ensembles

The evolution of a sample of noninteracting spin- $\frac{1}{2}$ nuclei in a static magnetic field obeys the Bloch equations (Cavanagh et al. 2006). In the presence of external magnetic fields (controls), the bulk magnetization is perturbed from the thermal equilibrium and evolves according to the controlled Bloch model, given by

$$\frac{d}{dt}M(t) = [\omega_0\Omega_z + u(t)\Omega_y + v(t)\Omega_x]M(t), \quad (1)$$

where $M(t) = (M_x(t), M_y(t), M_z(t))$ denotes the magnetization vector at time t , ω_0 is the Larmor frequency, and $(u(t), v(t))$ is the pair of external radiofrequency (rf) fields, referred to as pulses, applied in the y and x axis, respectively; the matrices

$$\Omega_x = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{bmatrix}, \quad \Omega_y = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 0 \end{bmatrix},$$

$$\Omega_z = \begin{bmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix},$$

are the generator of rotations around the x , y , and z axis, respectively. Conventionally, $M(t)$ is normalized to 1, i.e., $\|M(t)\| = 1$ for all $t \geq 0$.

The Bloch model in (1) is an idealization assuming that all spins in the ensemble have an identical Larmor frequency and that the rf pulses are applied uniformly to each spin. However, in

practice, e.g., in NMR experiments, variations appear in these quantities across the spin ensemble due to inhomogeneities in chemical environments, relaxation rates, and applied control fields. This leads to the consideration of a modified Bloch model as an ensemble control system of the form

$$\frac{d}{dt}M(t, \omega, \varepsilon) = [\omega\Omega_z + \varepsilon u\Omega_y + \varepsilon v\Omega_x]M(t, \omega, \varepsilon), \quad (2)$$

where $M(t, \omega, \varepsilon)$ denotes the magnetization at time t of the spin characterized by the parameter vector $\beta = (\omega, \varepsilon)$ with $\omega \in [\omega_1, \omega_2]$ and $\varepsilon \in [1 - \delta, 1 + \delta]$, $0 < \delta < 1$, modeling Larmor dispersion and rf inhomogeneity, respectively (Li and Khaneja 2006). In practice, the range of ^{13}C chemical shift leading to Larmor dispersion can be up to 40 kHz, and the rf field at the ends of the coil can be as low as 60% of that at the center of the coil (Li et al. 2011; Bernstein et al. 2004).

Ensemble Control Problems of Pulse Design

A typical problem in quantum control is to steer a large quantum ensemble from an initial state (configuration) $M(0, \omega, \varepsilon)$ at $t = 0$ to, or as close as possible to, a desired target state (configuration) $M_F(\omega, \varepsilon)$ at some time $T > 0$ using a common control input broadcast to the entire population. Practical constraints, such as power and time limitations as well as path and terminal constraints, require the consideration of optimal control problems involving the ensemble system in (2).

Ensemble Controllability

The emergence of ensemble systems was accompanied by a new generation of challenges in control theory, among which the notion of ensemble controllability (Li and Khaneja 2009) has drawn significant attention toward the development of unconventional methods for a comprehensive analysis (Li 2011). Controllability of spin ensembles as in (2) was analyzed through

the mapping of the analysis to a problem of polynomial approximation by utilizing the techniques from Lie theory (Li and Khaneja 2006; Li 2011). This transformation enabled a holistic pulse design methodology. On a practical point of view, controllability of a spin ensemble guarantees the existence of pulses for engineering arbitrary state configurations or patterns in the ensemble.

Pulse-Enabled Pattern Formation

The basic but premier pulse design enabling a wide variety of applications in quantum science and engineering, e.g., NMR spectroscopy, MRI, and quantum information processing, is the broadband pulse that uniformly or selectively excite or invert a spin population in the presence of Larmor dispersion or rf inhomogeneity (Glaser et al. 1998; Pryor 2006). More demanding tasks may be required for more specific applications, for example, fast quantum excitation in protein NMR spectroscopy for mitigation of relaxation effects and multiple slice-selective excitation in MRI for simultaneous scanning in the presence of both Larmor dispersion and rf inhomogeneity (Kobzar et al. 2005). An illustration of a

pattern excitation is displayed in Fig. 1, where the excitation profile depends on both Larmor dispersion and rf inhomogeneity.

Generation of Parameter-Dependent Rotations

Since the evolution of the spin ensemble, described in (2), depends on the system parameters, the key to pulse design for achieving the desired state transition or pattern formation is to synthesize parameter-dependent rotations. To fix ideas, let's consider the case of designing uniform and selective excitation pulses in the presence of rf inhomogeneity without Larmor dispersion. In this case, the spin dynamics follow the Bloch model as in (2), which, in the rotating frame with respect to Larmor frequency ω , obeys

$$\frac{d}{dt}M(t, \varepsilon) = \varepsilon[u(t)\Omega_y + v(t)\Omega_x]M(t, \varepsilon). \quad (3)$$

We first observe that one can write the solution to (3) as a product of a sequence of ε -dependent rotations, i.e., $M(t, \varepsilon) = U(t, \varepsilon)M(0, \varepsilon)$, where the total rotation $U(t, \varepsilon) = U_n(t_n, \varepsilon) \cdots U_2(t_2, \varepsilon)U_1(t_1, \varepsilon)$, where $t = \sum_{k=1}^n t_k$. We also know that applying constant controls $u(t) = u_k$ and $v(t) = v_k$ for time t_k to the ensemble system (3)

Pattern Formation in Spin Ensembles, Fig. 1 An (ω, ε) -pattern excitation of a spin ensemble. In this case, a pulse robust to both Larmor dispersion and rf inhomogeneity is sought to excite the ensemble from an initial state to the desired double-excitation pattern

generality is sought to excite the ensemble from an initial state to the desired double-excitation pattern

yields ε -dependent rotations, $\exp(\varepsilon u_k t_k \Omega_y)$ and $\exp(\varepsilon v_k t_k \Omega_x)$ around the y and x axis, respectively. Consequently, a sequence of such constant controls can be used to produce the following ε -dependent rotations:

$$U_{1k} = \exp(-\varepsilon \lambda_k \Omega_x) \exp(\varepsilon \frac{\beta_k}{2} \Omega_y) \exp(\varepsilon \lambda_k \Omega_x), \quad (4)$$

$$U_{2k} = \exp(\varepsilon \lambda_k \Omega_x) \exp(\varepsilon \frac{\beta_k}{2} \Omega_y) \exp(-\varepsilon \lambda_k \Omega_x), \quad (5)$$

for $k = 1, 2, \dots, n$, where $\lambda_k = v_k t_k$ and $\beta_k = 2u_k t_k$, and t_k , u_k , and v_k are parameters. If β_k is small enough such that $U_{1k} U_{2k} \approx U_{2k} U_{1k}$, then the propagator $U_k \doteq U_{2k} U_{1k} \approx \exp[\varepsilon \beta_k \cos(\varepsilon \lambda_k) \Omega_y]$, which approximates an ε -dependent rotation around the y axis of the angle $\varepsilon \beta_k \cos(\varepsilon \lambda_k)$. This approximation is referred to as the *small angle approximation* (Pryor 2006; Zhang and Li 2015). The intuition behind this sequential approximation is to reduce the distortion in each rotation angle caused by rf inhomogeneity.

Following this synthesis procedure, one can generate an ε -dependent total rotation

$$\begin{aligned} U(t, \varepsilon) &= \prod_{k=1}^n U_k(t, \varepsilon) \\ &= \exp \left[\sum_{k=1}^n \varepsilon \beta_k \cos(\varepsilon \lambda_k) \Omega_y \right]. \end{aligned} \quad (6)$$

By an appropriate choice of the parameters β_k and λ_k , any desired ε -dependent rotation around the y axis, $\theta(\varepsilon)$, can be produced by using piecewise constant controls $\{u_k, v_k\}$ such that $\sum_{k=1}^n \varepsilon \beta_k \cos(\varepsilon \lambda_k) \approx \theta(\varepsilon)$. This approximation synthesis procedure illuminates the use of *non-harmonic Fourier series* for pulse design (Zhang and Li 2015; Zhang et al. 2019). Similarly, rotations around the x or the z axis, and thus any three-dimensional rotations, can be synthesized based on the same procedure.

Coherence Transfer in Spin Networks

Coherence transfer between coupled spins is a vital step to multidimensional NMR spectroscopy and quantum information processing (Khaneja et al. 2004; Cavanagh et al. 2006). The small angle approximation and the non-harmonic Fourier series-based approach are directly applicable to design pulses for robust coherence transfer in a network of coupled spins. Here, we illustrate the idea by considering the design of pulses that compensate for variation in the J -coupling constant, which occurs in applications involving large proteins. The coherence transfer can be modeled as an ensemble control problem, given by

$$\frac{d}{dt} X(t, J) = A(t, J) X(t, J), \quad (7)$$

where $X(t, J) \in \mathbb{R}^6$ denotes the state of the two spins,

$$\begin{aligned} A(t, J) &= \begin{bmatrix} 0 & -v(t) & u(t) & 0 & 0 & 0 \\ v(t) & 0 & 0 & -J & 0 & 0 \\ -u(t) & 0 & 0 & 0 & J & 0 \\ 0 & -J & 0 & 0 & 0 & -u(t) \\ 0 & 0 & -J & 0 & 0 & v(t) \\ 0 & 0 & 0 & u(t) & -v(t) & 0 \end{bmatrix} \\ &= J(\Omega_{24} - \Omega_{35}) + u(t)(\Omega_{46} - \Omega_{13}) + v(t)(\Omega_{12} - \Omega_{56}), \end{aligned}$$

with $\Omega_{ij} \in \mathbb{R}^{6 \times 6}$ being the matrix with -1 in the ij th entry and 0 elsewhere, and $J \in [1 - \delta, 1 + \delta]$, $0 < \delta < 1$, denotes the coupling between the two spin systems. Observe that we may treat $P_1 \doteq \Omega_{24} - \Omega_{35}$ and $P_2 \doteq \Omega_{12} - \Omega_{56}$ as Ω_x and Ω_y , respectively, in comparison with the case studied above for the system in (3), and then proceed with the same scheme of small angle approximation and non-harmonic Fourier series expansion to reach the desired J -dependent propagation. Specifically, by letting $U_{1k} = \exp(\lambda_k J P_1) \exp(\frac{\beta_k}{2} P_2) \exp(-\lambda_k J P_1)$ and $U_{2k} = \exp(-\lambda_k J P_1) \exp(\frac{\beta_k}{2} P_2) \exp(\lambda_k J P_1)$, small angle approximations yield

$$U(t, J) = \prod_{k=1}^n U_k(t, J) \\ = \exp\left(\sum_{k=1}^n \beta_k \cos(\lambda_k J) P_2\right). \quad (8)$$

Note that another routine of small angle approximations needs to be implemented to resolve the involvement of the drift term P_2 in (8) (Zhang et al. 2019).

Alternating Optimization for Optimal Pulse Synthesis

The generated parameter-dependent evolution as in (6) and (8) will be used to synthesize optimal pulses. A natural way to achieve this is to formulate the non-harmonic Fourier approximation as an optimization problem on a Hilbert space. For example, the case in (6) is formulated as

$$\min_{\beta, \lambda} J(\beta, \lambda) = \left\| \phi(\varepsilon) - \sum_{k=1}^n \beta_k \cos(\lambda_k \varepsilon) \right\|_2^2, \quad (9)$$

where $\phi(\varepsilon) = \theta(\varepsilon)/\varepsilon$, $\beta = (\beta_1, \dots, \beta_n) \in \mathbb{R}^n$, $\lambda = (\lambda_1, \dots, \lambda_n) \in \mathbb{R}^n$, and $\|\cdot\|_2$ denotes the L^2 -

norm on the Hilbert space $\mathcal{H} = L^2([1 - \delta, 1 + \delta])$, i.e., $\|f\|_2 = \sqrt{\int_{1-\delta}^{1+\delta} |f(\varepsilon)|^2 d\varepsilon}$. The solution (β, λ) then determines the pulse sequence through the relations $u_k = \beta_k/2t_k$ and $v_k = \lambda_k/t_k$. Most importantly, this optimization problem can be effectively solved by using an alternating minimization approach, alternating between the decision variables β and λ (Zhang and Li 2015).

A uniform excitation $(\pi/2)$ pulse that compensates for a 40% variation in the strength of the applied rf field constructed by solving the optimization problem in (9) is illustrated in Fig. 2, where the order of the non-harmonic Fourier series was 3 ($n = 3$), and the piecewise constant control sequences $\{u_k, v_k\}$ were calculated, which steer the spin ensemble in (3) with $\varepsilon \in [0.6, 1.4]$ from $M(0, \varepsilon) = (0, 0, 1)'$ to $M_F(\varepsilon) = (1, 0, 0)'$ at time $T = 1.4$. The duration of the pulse, T , depends on the optimized non-harmonic Fourier coefficients, i.e., $T = \sum_{k=1}^n (|\frac{\beta_k}{u_0}| + 4|\frac{\lambda_k}{v_0}|)$. A selective excitation pulse that created the excitation pattern,

$$\phi(\varepsilon) = \begin{cases} \frac{\pi}{2\varepsilon}, & 0.9 \leq \varepsilon \leq 1.1 \\ 0, & 0.6 \leq \varepsilon < 0.9, \quad 1.1 < \varepsilon \leq 1.4, \end{cases} \quad (10)$$

Pattern Formation in Spin Ensembles, Fig. 2 The final profile of $M_x(T, \varepsilon)$ at $T = 1.4$ of the spin ensemble in (3) for $\varepsilon \in [0.6, 1.4]$ following the uniform $\pi/2$ pulse

constructed using three ($n = 3$) non-harmonic Fourier terms, i.e., $\theta(\varepsilon)/\varepsilon \approx \sum_{k=1}^n \beta_k \cos(\lambda_k \varepsilon)$

Pattern Formation in Spin Ensembles, Fig. 3 The selective excitation pattern was created by using a pulse designed using 15 ($n = 15$) non-harmonic Fourier terms, which generated the desired ε -dependent rotations as in (10)

is shown in Fig. 3, where spins experiencing different rf intensity were selectively excited.

Summary and Future Directions

Ensemble control lays a rigorous and systematic platform for robust control of quantum ensembles. Unconventional control problems, such as pulse design arising from the quantum domain, emerged from other remote fields as well, for example, in neuroscience, cell- and chronobiology, and social networks. These emerging problems require innovations and investments in developing integrated and out-of-the-box methods. Major challenges remain, especially to investigate optimal control and learning problems involving quantum ensembles (in particular open quantum systems) or more general ensemble systems, understand fundamental limits on the ability to control ensemble systems and further explore structural control properties and utilize structures to control ensembles.

Abstract

Perturbation analysis (PA) is a systematic methodology for estimating the sensitivities (gradients) of performance measures in discrete event systems (DES) with respect to various model or control parameters of interest. PA takes advantage of the special structure of DES sample realizations and is based entirely on observable system data. In particular, it does not require knowledge of the stochastic characterizations of the random processes involved and is simple to implement in a nonintrusive manner. PA estimators, therefore, enable implementations for real-time control in addition to off-line optimization. This entry presents the main ideas and statistical properties of PA techniques for both DES and their recent generalizations to stochastic hybrid systems (SHS), especially for the simplest class of sensitivity estimators known as infinitesimal perturbation analysis (IPA).

Keywords

Gradient estimation · Sample-path techniques · Sensitivity analysis · Discrete event systems · Hybrid dynamical systems

Introduction

Sensitivity analysis is an essential component of the system design process in a wide variety of application areas. In essence, it provides

quantitative variations of performance metrics resulting from possible perturbations in design set points and hence can be used in *optimization and control* as well as provide measures of performance robustness. *Perturbation analysis* (PA) is a systematic technique for computing sample-based sensitivity estimators of performance metrics in discrete event systems (DES) by using the special properties of their sample realizations. The effectiveness of such estimators (e.g., unbiasedness) depends on the characteristics of the DES to which PA is applied and on the specific performance metric of interest. The purpose of this entry is to present and explain some of the main ideas and fundamental techniques of PA.

Figure 1 depicts an abstract schematic where the operation of a stochastic system depends on a parameter θ that is chosen from a given set Θ . Let $J(\theta)$ be an expected-value performance function of the system, and suppose that $J(\theta) = E[L(\theta)]$, where $E[\cdot]$ denotes expectation and $L(\theta)$ is a sample realization computable from a sample path of the system. In many situations $J(\theta)$ lacks a closed-form expression, and its sample realization, $L(\theta)$, provides the most practical way for its estimation. Applications of sensitivity analysis often concern the effects of perturbations in the parameter θ on the sample realization $L(\theta)$. Denoting such perturbations by $\Delta\theta$, their effects can be characterized by the difference term $L(\theta + \Delta\theta) - L(\theta)$. PA provides such difference terms from the *same* sample path that was used for computing $L(\theta)$. Furthermore, if $\theta \in R^n$ and the function $L(\cdot)$ is differentiable, then PA can compute the gradient-term $\nabla L(\theta)$ from the same sample path. These sample-path-based sensitivities can be used, under suitable conditions, to estimate the quantities $J(\theta + \Delta\theta) - J(\theta)$ and $\nabla J(\theta)$, respectively.

The PA theory was pioneered by Yu-Chi Ho who led its eventual development by his group

Perturbation Analysis of Discrete Event Systems, Fig. 1 Framework for perturbation analysis (PA)

and other researchers over two decades. The early works were motivated by optimal resource management problems in manufacturing and concerned the effects of buffer allocation on throughput in transfer lines (Ho et al. 1979; Ho and Cassandras 1983). Subsequently PA was developed in the setting of queueing networks by virtue of their wide use as models in applications. In this setting, typically θ is a set-point parameter affecting service times, inter-arrival times, routing fractions, buffer sizes, and various flow-control laws; $J(\theta)$ is an expected-value performance metric like average delay, throughput, and loss; and $L(\theta)$ is a sample realization of $J(\theta)$. The special structure of sample paths of queueing networks often yields simple PA algorithms for the difference terms $L(\theta + \Delta\theta) - L(\theta)$, as well as the gradient term $\nabla L(\theta)$, from the common sample path. The PA techniques for computing $L(\theta + \Delta\theta) - L(\theta)$ are collectively referred to as *finite perturbation analysis* (FPA), while those for computing $\nabla L(\theta)$ are called *infinitesimal perturbation analysis* (IPA) (Ho et al. 1983). Much of the development of PA has focused on IPA, rather than FPA, due to its greater simplicity and natural use in optimization, and hence it will be the focal point of this entry. For comprehensive expositions of PA and its various techniques, please see Ho and Cao (1991), Glasserman (1991), and Cassandras and Lafortune (2008).

The purpose of the IPA gradient, $\nabla L(\theta)$, is to estimate $\nabla J(\theta)$. This, however, can be useful only as long as $\nabla L(\theta)$ is an unbiased realization of $\nabla J(\theta)$, namely,

$$E[\nabla L(\theta)] = \nabla E[L(\theta)] = \nabla J(\theta),$$

and in this case, it is said that *IPA is unbiased* (Cao 1985). Since $J(\theta) = E[L(\theta)]$, unbiasedness means the commutativity of the operators of differentiation with respect to θ and integration (expectation) in the probability space, and this is closely related to the condition that, with probability one (w.p.1), the random function $L(\theta)$ is continuous throughout Θ . As a matter of fact, the two conditions are practically synonymous. However, shortly after the emergence of IPA, it became apparent that in many

queueing models of interest, $L(\theta)$ is not continuous, and hence IPA is not unbiased (Heidelberger et al. 1988). Subsequently various techniques to overcome this problem were explored, including so-called cut-and-paste of the sample paths and re-parametrization of the underlying probability space via statistical conditioning. For a more comprehensive coverage of such techniques, please see Cassandras and Lafortune (2008) and references therein. These techniques can yield unbiased gradient estimators in principle but often at the expense of prohibitive computing costs. Recently an alternative approach has emerged, based on *stochastic flow models* (SFM) that are comprised of fluid queues (Cassandras et al. 2002). It extends, significantly, the class of models and problems where IPA is unbiased and has the added advantage of yielding very simple gradient estimators.

The following sections of this entry present IPA in the general setting of DES, explain the limits of its scope in queueing models, describe alternative PA techniques for extending those limits, present the SFM approach, and conclude with some thoughts on current research directions.

DES Setting for IPA

IPA can be applied to any DES modeled as a stochastic timed automaton, defined in Cassandras and Lafortune (2008) and discussed in “► [Models for Discrete Event Systems: An Overview](#).” Briefly, a stochastic timed automaton is a six-tuple $(\mathcal{E}, \mathcal{X}, \Gamma, p, p_0, G)$, where $\mathcal{E}$ is an event set, $\mathcal{X}$ is a state space, and $\Gamma(x) \subseteq \mathcal{E}$ is the set of feasible events when the state is x , defined for all $x \in \mathcal{X}$. The initial state is drawn from $p_0(x) = P[X_0 = x]$. Subsequently, given that the current state is x , with each feasible event $i \in \Gamma(x)$, we associate a clock value Y_i , which represents the time until event i is to occur. Thus, comparing all such clock values, we identify the triggering event $E' = \arg \min_{i \in \Gamma(x)} \{Y_i\}$ where $Y^* = \min_{i \in \Gamma(x)} \{Y_i\}$ is the interevent time (the time elapsed since the last event occurrence). To simplify the notation, we define $e' := E'$. Thus, with e' determined, the state transition

probabilities $p(x'; x, e')$ are used to specify the next state x' . Finally, the clock values are updated: Y_i is decremented by Y^* for all i (other than the triggering event) which remain feasible in x' , while the triggering event (and all other events which are activated upon entering x') are assigned a new lifetime sampled from a distribution G_i . The set $G = \{G_i : i \in \mathcal{E}\}$ defines the stochastic clock structure of the automaton.

Let $T_{\alpha,n}$ denote the n th occurrence time of event $\alpha \in \mathcal{E}$, and let $V_{\alpha,n}$ denote a realization of the lifetime event distribution G_α such that $V_{\alpha,n} = T_{\alpha,n} - T_{\beta,m}$ for some (any) event $\beta \in \mathcal{E}$ and $m \in \{1, 2, \dots\}$. One can then always write $T_{\alpha,n} = V_{\beta_1,k_1} + \dots + V_{\beta_s,k_s}$ for some s . Let us now consider a parameter $\theta \in R$ which can only affect one or more of the event lifetime distributions $G_\alpha(x; \theta)$; in particular, θ does not affect the state transition mechanism. The case where $\theta \in R^n$ can be handled in similar ways, but the one-dimensional case permits us to use the derivative notation rather than the gradient symbol, which simplifies the presentation. Viewing lifetimes as functions of θ , $V_{\alpha,k}(\theta)$, it can be shown (under mild technical conditions, see Glasserman 1991) that

$$\frac{dV_{\alpha,k}}{d\theta} = - \frac{[\partial G_\alpha(x; \theta)/\partial \theta]_{(V_{\alpha,k}, \theta)}}{[\partial G_\alpha(x; \theta)/\partial x]_{(V_{\alpha,k}, \theta)}}, \quad (1)$$

where the subscript $(V_{\alpha,k}, \theta)$ indicates that the corresponding derivative of G_α is evaluated at the point $(V_{\alpha,k}, \theta)$. This describes how a perturbation in θ *generates* a perturbation in the associated event lifetime $V_{\alpha,k}$. Such a perturbation can now *propagate* through the DES to affect various event occurrence times according to the dynamics prescribed by the stochastic timed automaton. Event time derivatives $dT_{\alpha,n}(\theta)/d\theta$ are given by

$$\frac{dT_{\alpha,n}}{d\theta} = \sum_{\beta,m} \frac{dV_{\beta,m}}{d\theta} \eta(\alpha, n; \beta, m) \quad (2)$$

where $\eta(\alpha, n; \beta, m)$ is a triggering indicator taking values in $\{0, 1\}$ so that $\eta(\alpha, n; \beta, m) = 1$ if the n th occurrence of event α is triggered by the m th occurrence of β ; $\eta(\alpha, n; \alpha, n) = 1$ for all $\alpha \in \mathcal{E}$; $\eta(\alpha, n; \beta', m') = 1$ if $\eta(\alpha, n; \beta, m) = 1$

and $\eta(\beta, m; \beta', m') = 1$; and $\eta(\alpha, n; \beta, m) = 0$ otherwise.

This leads to a general-purpose algorithm for evaluating event time derivatives along an observed sample path (see Algorithm 1) of a DES modeled as a stochastic timed automaton. In particular, we define a perturbation accumulator, Δ_α , for every event $\alpha \in \mathcal{E}$. The accumulator Δ_α is updated at event occurrences in two ways: (i) it is incremented by $dV_\alpha/d\theta$ whenever an event α occurs, and (ii) it is coupled to an accumulator Δ_β whenever an event β (possibly $\beta = \alpha$) occurs that activates an event α . No particular stopping condition is specified, since this may vary depending on the problem of interest.

Algorithm 1 General-purpose IPA algorithm for stochastic timed automata

1. Initialization

If event α is feasible at x_0 : $\Delta_\alpha := dV_{\alpha,1}/d\theta$
 Else, for all other $\alpha \in \mathcal{E}$: $\Delta_\alpha := 0$
 2. Whenever event β is observed

If event α is activated with new lifetime V_α :

 - 2.1. Compute $dV_\alpha/d\theta$ through (1)
 - 2.2. $\Delta_\alpha := \Delta_\beta + dV_\alpha/d\theta$
-

Sample Function Derivatives Since many sample performance functions $L(\theta)$ of interest can be expressed in terms of event times $T_{\alpha,n}$, we can use (2) and Algorithm 1 in order to obtain derivatives of the form $dL(\theta)/d\theta$. As an example, a large class of such functions is of the form

$$L_T(\theta) = \int_0^T C(x(t, \theta)) dt$$

where $C(x(t, \theta))$ is a bounded cost associated with operating the system at state $x(t, \theta)$. Then,

$$\frac{dL_T}{d\theta} = \sum_{k=1}^{N(T)} \frac{dT_k}{d\theta} [C(x_{k-1}) - C(x_k)]$$

where $N(T)$ counts the total number of events observed in $[0, T]$ and x_k is the state remaining

fixed in any interval $(T_k, T_{k+1}]$ with $T_k = T_{\alpha,n}$ for some $\alpha \in \mathcal{E}, n = 1, 2, \dots$

Estimation of Performance Measure Derivatives Using $dL_T(\theta)/d\theta$ from above, we can obtain unbiased estimates of $dJ/d\theta$ if the following condition holds:

$$\frac{dJ(\theta)}{d\theta} = E \left[\frac{dL_T(\theta)}{d\theta} \right].$$

As mentioned earlier, this key condition is closely related to the continuity of the sample performance functions. A discontinuity often is caused by a swap in the order of two events that results from small variations in θ and yields different future state trajectories. However, it is possible that the future state trajectory following the occurrence of the two events is invariant under their order, and in this case, the two events are said to *commute*. This commuting condition, defined by Glasserman, was shown to be identical, under broad assumptions, to the continuity of the sample functions $L(\theta)$ and hence to the unbiasedness of IPA (Glasserman 1991).

The main ideas discussed in this section will next be illustrated on a simple queue.

Queueing Example

Consider the IPA gradient (derivative) of the expected sojourn time (delay) in a GI/G/1 queue with respect to a real-valued parameter of its arrival process. Assume that the queue is empty at time $t = 0$, and it serves its customers according to the order of their arrivals. Let us denote by $a_k, k = 1, 2, \dots$, the arrival times, and by $s_k, k = 1, 2, \dots$, the service times of consecutive customers. Furthermore, we denote by $v_k, k = 1, 2, \dots$, the k th inter-arrival time, namely, $v_k = a_k - a_{k-1}$, where $a_0 := 0$. Observe that the queue is a stochastic timed automaton as defined earlier, with event space $\{arrival, departure\}$, state space $\{0, 1, \dots\}$ representing the queue's occupancy, and feasible event set $\{arrival\}$ when $x = 0$ and $\{arrival, departure\}$ when $x > 0$.

Let $\theta \in \mathcal{R}$ is a parameter of the distribution of the inter-arrival times, and hence the realizations

of v depend on θ in a functional manner. For example, if the arrival process is Poisson and θ is its rate, then a realization of the inter-arrival times has the form $v = -\theta \ln(1 - \omega)$, where $\omega \in [0, 1]$ is a uniform variate. To emphasize the dependence of v on θ , we denote it by $v(\theta)$, while its dependence on ω is implicit. Similarly, the arrival times depend on θ and hence denoted by $a_k(\theta)$, but the service times s_k do not depend on θ . The departure time of the k th customer and its delay depend on θ and are denoted by $d_k(\theta)$ and $D_k(\theta)$, respectively. The forthcoming paragraphs discuss the derivatives of these functions with respect to θ ; we use the prime symbol to indicate such derivatives in order to simplify the notation.

Define the sample performance function

$$L_N(\theta) := N^{-1} \sum_{k=1}^N D_k(\theta)$$

for a given $N > 0$. Under stability conditions, $\lim_{N \rightarrow \infty} L_N(\theta) = J(\theta)$ w.p.1, where $J(\theta)$ denotes the mean of the delay's stationary distribution. The role of IPA is to estimate $J'(\theta)$ via the sample derivative $L'_N(\theta)$, and this is justified as long as $\lim_{N \rightarrow \infty} L'_N(\theta) = J'(\theta)$ w.p.1. In this case, IPA is said to be *strongly consistent*. In contrast, unbiasedness pertains to the performance function $J_N(\theta) := E[L_N(\theta)]$ and means that $E[L'_N(\theta)] = J'(\theta)$. The concepts of strong consistency and unbiasedness are closely related except that the latter concerns finite-horizon processes while the former pertains to stationary distributions in steady state. Both concepts have been extensively investigated in recent years: strong consistency in the setting of Markov chains and Markov decision processes ([► Perturbation Analysis of Steady-State Performance and Relative Optimization](#), Cao 2007) and unbiasedness in the context of stochastic hybrid systems, as will be described in the sequel. We will focus the rest of the discussion on the issue of unbiasedness.

Since $L_N(\theta) = N^{-1} \sum_{k=1}^N D_k(\theta)$, its IPA derivative is $L'_N(\theta) = N^{-1} \sum_{k=1}^N D'_k(\theta)$, and since $D_k(\theta) = a_k(\theta) - d_k(\theta)$, it follows that $D'_k(\theta) = a'_k(\theta) - d'_k(\theta)$. The last two derivative

terms are computable via the following recursive procedures. First, $a_k(\theta) = a_{k-1}(\theta) + v_k(\theta)$, and hence

$$a'_k(\theta) = a'_{k-1}(\theta) + v'_k(\theta).$$

The term $v'_k(\theta)$ has to be obtained directly from the realization of v , and this often is possible since such realizations depend functionally on θ ; for instance, in the previous example, $v = -\theta \ln(1 - \omega)$, and hence $v'(\theta) = -\ln(1 - \omega)$. Next, $d_k(\theta)$ is given by the Lindley equation

$$d_k(\theta) = \max \{a_k(\theta), d_{k-1}(\theta)\} + s_k,$$

and therefore, denoting by ℓ_k the index of the customer that started the busy period containing customer k , we have that

$$d'_k(\theta) = a'_{\ell_k}(\theta).$$

From these recursive relations, it follows that $D'_k(\theta) = 0$ if customer k starts a busy period and $D'_k(\theta) = -\sum_{i=\ell_k+1}^k v'_i(\theta)$ if customer k does not start a busy period.

These equations shed light on the structure of IPA in a general class of queueing networks. First there is the *perturbation generation*, namely, the sampling of derivative (gradient) terms directly from the sample sequence of variates (ω) which define the sample path; that was $v'(\theta)$ in the above example. These terms drive the recursive equations that yield the IPA derivatives. The recursive equations often are based on the tracking of certain events such as the start of busy periods or idle periods, and the process of tracking the derivatives through them is referred to as *perturbation propagation*. In the above example, it is obvious how the perturbation propagation tracks the busy periods at the queue. Furthermore, in a network setting, the perturbations can propagate from one queue to the next in a natural fashion. For instance, suppose that customers departing from the queue analyzed above enter a second queue. Then the derivative terms $d'_k(\theta)$ of the upstream queue act as the derivative terms $a'_k(\theta)$ of the downstream queue. This structure of perturbations' generation and propagation through the tracking of busy periods and other events

Perturbation Analysis of Discrete Event Systems,
Fig. 2 Queue with two customer classes

often yields simple recursive algorithms for computing the IPA derivatives.

Concerning the issue of unbiasedness, it is clear that in the above example, the sample function $L_N(\theta)$ is continuous in θ , and hence IPA is unbiased. However, in many systems of interest, the IPA derivative is biased. For example, consider the two-input, single-server queue shown in Fig. 2, where customers are served according to their arrival order regardless of source. Suppose that θ is a parameter of the upper arrival process but not of the lower arrival process and denote the respective inter-arrival times of the input streams by $v_{1,k}(\theta)$, $k = 1, 2, \dots$, and $v_{2,m}$, $m = 1, 2, \dots$, as indicated in the figure. Furthermore, let $d_{1,k}(\theta)$ denote the departure time from the queue of the k th customer that came from the upper source, and let $d_{2,m}(\theta)$ denote the departure time from the queue of the m th customer that came from the lower source. Similarly, let $D_{1,k}(\theta)$ and $D_{2,m}(\theta)$ be the delays of the k th customer from the upper source and the m th customer from the lower source, respectively. Lastly, in analogy with the previous example, consider the sample performance functions $L_{1,N}(\theta) := N^{-1} \sum_{k=1}^N D_{1,k}(\theta)$ and $L_{2,N}(\theta) := N^{-1} \sum_{m=1}^N D_{2,m}(\theta)$.

The IPA derivatives $L'_{1,N}(\theta)$ and $L'_{2,N}(\theta)$ have quite similar expressions to those derived earlier, but they are not unbiased. To see this point, suppose that $v_{1,k}(\cdot)$ is a monotone increasing function of θ , and consider the functions $a_{1,k}(\theta)$, $d_{1,k}(\theta)$, and $d_{2,k}(\theta)$ for a common sample path. Suppose that at some point $\bar{\theta}$ the order of arrivals of the n th customer from the upper source and the m th customer from the lower source is swapped. Then the service order of these customers will be swapped as well, inducing discontinuities in $d_{1,k}(\theta)$ and $d_{2,m}(\theta)$ at the point $\theta = \bar{\theta}$. Consequently, the sample performance functions $L_{1,N}(\theta)$ and $L_{2,N}(\theta)$ also will be

discontinuous at $\theta = \bar{\theta}$, and hence their IPA derivatives are biased. Furthermore, if the queue is a part of a network and its output process directs customers to other queues, then the discontinuities in the various traffic processes will propagate downstream.

The causes of bias of IPA in queueing networks include multiple customer classes, non-Markovian routing, and loss (spillover) due to finite buffers. This leaves a limited class of networks where IPA can be unbiased and hence useful in applications. The following sections describe various approaches developed for enlarging the class of systems where IPA is unbiased.

IPA Extensions

When IPA fails (because the commuting condition is violated or a sample function exhibits discontinuities in θ), one can still use the PA approach to derive unbiased performance sensitivity estimates. There are two ways to accomplish this: (i) by modifying the stochastic timed automaton model so that IPA is “made to work” and (ii) by paying the price of more information collected from the observed sample path, in which case the same essential PA philosophy can lead to unbiased and strongly consistent estimators, but these are no longer as simple as IPA ones. Regarding (i), the main idea here is that there may be more than one way to construct (statistically equivalent) sample paths of a stochastic DES, and while one way leads to discontinuous sample functions $L(\theta)$, another does not; a variety of such ways is provided in Cassandras and Lafortune (2008). Regarding (ii), the methodology of *smoothed perturbation analysis* (SPA) (Gong and Ho 1987) provides a generalization of IPA in which more information is extracted from a DES sample path in order to gain some knowledge about the magnitude of jumps in $L(\theta)$.

The main idea of SPA lies in the “smoothing property” of conditional expectation. If we are willing to extract information from a sample path and denote it by Z , called the *characterization* of

the sample path, then we can evaluate, not just the sample function $L(\theta)$ but also the conditional expectation $E[L(\theta) \mid \mathcal{Z}]$ (provided we have some distributional knowledge based on which this expectation can be evaluated). This can result in a smoother function of θ than $L(\theta)$. Thus, starting with the condition for an IPA estimator to be unbiased,

$$\nabla J(\theta) = E[\nabla L(\theta)],$$

we rewrite the right-hand side above as shown below, replacing $E[L(\theta)]$ by the expectation of a conditional expectation:

$$\nabla J(\theta) = \nabla E[L(\theta)] = \nabla E[E[L(\theta) \mid \mathcal{Z}]] \quad (3)$$

where the inner expectation is a conditional one, and the conditioning is on the characterization $\mathcal{Z}$. Treating $E[L(\theta) \mid \mathcal{Z}]$ as the new sample function, we expect it to be “smoother” than $L(\theta)$, and, in particular, continuous in θ . Then, under some additional conditions (comparable to those made in the development of IPA) the interchange of differentiation and expectation in (3) can be justified:

$$\nabla J(\theta) = E[\nabla E[L(\theta) \mid \mathcal{Z}]].$$

Letting $L_{\mathcal{Z}}(\theta) := E[L(\theta) \mid \mathcal{Z}]$, the SPA estimator of $\nabla J(\theta)$ is

$$[\nabla J(\theta)]_{SPA} = \nabla L_{\mathcal{Z}}(\theta). \quad (4)$$

Naturally, the idea is to minimize the amount of added information represented by $\mathcal{Z}$, since this incurs added costs we would like to avoid. The choice of the characterization $\mathcal{Z}$ generally depends on the sample function considered and the system under study.

A number of other extensions to IPA have also been developed (see Cassandras and Lafortune 2008). It is also worth mentioning that the PA approach can be applied to a parameter θ taking values from a finite set $\Theta = \{\theta_0, \theta_1, \dots, \theta_M\}$. The theory of *concurrent estimation* and *sample path constructability* provides techniques to estimate performance measures of the DES through

the process of constructing sample paths under each of $\theta_0, \theta_1, \dots, \theta_M$; for details see Cassandras and Lafortune (2008).

SFM Framework for IPA

The stochastic flow model (SFM) framework essentially consists of fluid queues which forego the notion of the individual customer and focus instead on the aggregate flow. In such a fluid queue, traffic and service processes are characterized by instantaneous flow rates as opposed to the arrival, departure, and service times of discrete customers. The SFM qualifies as a *stochastic hybrid system* with bilayer dynamics: discrete event dynamics at the upper layer and time-driven dynamics at the lower layer. The discrete events are associated with abrupt (discontinuous) changes in traffic-flow processes, such as the boundaries of busy periods at the queues. In contrast, the time-driven dynamics describe the continuous evolution of flow rates between successive discrete events, usually by differential equations or explicit functional terms. Performance metrics that are natural to SFMs typically reflect quantitative measures of flow rates, like average throughput, buffer workload, and loss.

Due to the smoothing effects of SFMs, they appear to provide a far more natural setting for IPA than their analogous discrete-queueing counterparts. Furthermore, their IPA gradients often are computable via extremely simple algorithms that are based entirely on the observed sample path. Consequently SFMs could, in principle, be implemented on the sample paths generated by an actual system rather than simulations thereof and thus be used in real-time optimization.

All of this will be explained via a concrete example of a queue which, though simple, captures the salient features of the SFM setting for IPA. For a more comprehensive discussion, please see (Cassandras et al. 2010; Wardi et al. 2010; Yao and Cassandras 2013).

Consider the fluid queue depicted in Fig. 3 whose input and output flow rate processes are denoted, respectively, by $\alpha(t)$ and $\delta(t)$. The output-flow process depends on the input-flow

Perturbation Analysis of Discrete Event Systems, Fig. 3 Basic SFM

process via the action of the server as well as the buffer size. The server is characterized by an instantaneous processing rate, denoted by $\beta(t)$, and the buffer size, namely, the maximum amount of fluid the buffer can hold, is denoted by c . Fluid overflow occurs when the inflow (arrival) rate exceeds the service rate while the buffer is full, and the overflow (loss) rate is denoted by $\gamma(t)$.

Suppose that $\alpha(t)$ and $\beta(t)$ are random functions defined on a suitable probability space, and assume that they are piecewise continuous and of bounded variation w.p.1. In order to describe their functional relations to $\delta(t)$ and $\gamma(t)$, we define the state variable to be the amount of fluid in the buffer (workload), and denote it by $x(t)$. The dynamics of the system evolve according to the following one-sided differential equation:

$$\frac{dx}{dt^+} = \begin{cases} 0, & \text{if } x(t) = 0 \text{ and } \alpha(t) \leq \beta(t) \\ 0, & \text{if } x(t) = c \text{ and } \alpha(t) \geq \beta(t) \\ \alpha(t) - \beta(t), & \text{otherwise,} \end{cases}$$

and $\delta(t)$ and $\beta(t)$ are related to $\alpha(t)$ and $\gamma(t)$ via

$$\delta(t) = \begin{cases} \beta(t), & \text{if } x(t) > 0 \\ \alpha(t), & \text{if } x(t) = 0, \end{cases}$$

and

$$\gamma(t) = \begin{cases} \alpha(t) - \beta(t), & \text{if } x(t) = c \\ 0, & \text{if } x(t) < c. \end{cases}$$

Network arrangements of such fluid queues, with specified routing and control schemes, provide a rich class of SFMs.

Let $\theta \in \mathcal{R}$ be a parameter of the inflow rate, the service rate, or a network control law; for instance, θ can be the *on* time of the flow from an off/on source, a uniform rate of the server, or the threshold level in a threshold-based flow control.

Then the aforementioned traffic processes are functions of θ and t and hence are denoted by $\alpha(\theta; t)$, $\beta(\theta; t)$, $x(\theta; t)$, etc. Fix the parameter θ , and consider the evolution of the system over a given time horizon, $[0, T]$. Performance measures of interest in applications include the average loss rate over the horizon $[0, T]$ and the average workload there which is related to the delay by Little's Law. Related to them are the sample performance functions $L_{\gamma, T}(\theta) := \int_0^T \gamma(\theta, t) dt$ and $L_{x, T}(\theta) := \int_0^T x(\theta, t) dt$; the former is called the *loss volume* and the latter the *cumulative workload*.

To illustrate the forms of their IPA derivatives, consider the basic SFM shown in Fig. 3, and let θ be its buffer size, namely, $\theta = c$. We say that a busy period of the queue is *lossy* if it incurs some loss at any amount. Let us denote by N_T the number of lossy busy periods in the horizon $[0, T]$. Then (see Cassandras et al. 2002), the IPA derivative of the loss volume has the following form:

$$L'_{\gamma, T}(\theta) = -N_T,$$

where again we use the prime symbol to denote derivative with respect to θ . This formula amounts to a counting process and indeed it is very simple. As an example, Fig. 4 depicts a typical state trajectory derived from a sample path. It is readily seen that the first busy period is lossy, while the second one is not, and therefore, $L'_{\gamma, T}(\theta) = -1$.

Concerning the cumulative workload, suppose that the queue has M lossy busy periods in the time interval $[0, T]$, and let us enumerate them by the counter $m = 1, \dots, M$. Moreover, denote by u_m the first time the buffer becomes full in its m th lossy busy period and by v_m the end time of that busy period. Then (see Cassandras et al. 2002),

Perturbation Analysis of Discrete Event Systems, Fig. 4 State trajectory of the SFM

$$L'_{x,T}(\theta) = \sum_{m=1}^M (v_m - u_m).$$

In the example provided by Fig. 4, $L'_{x,T}(\theta) = v_1 - u_1$.

These equations for the IPA derivatives not only are very simple but require no knowledge of the specific form of the processes $\{\alpha(t)\}$ or $\{\beta(t)\}$, their realizations, or underlying probability law. They depend only on limited information which is directly observed from the sample path and hence are said to be *nonparametric* or *model-free*. Furthermore, they have been shown to possess considerable robustness to modeling variations that do not cause significant alterations of the busy periods of the queue. A case of interest is when the SFM formalism is used as an abstraction of a queue. Then the above IPA formulas that were derived from an analysis of the SFM can be successfully applied to sample paths that are generated from the discrete queue. This is in contrast to the IPA formulas that are derived from the discrete queue, which generally are highly biased.

All of these properties of IPA in the SFM setting, including its unbiasedness, simplicity, the nonparametric nature of its algorithms, and its robustness to model variations, have had extensions to SFM networks and systems beyond the basic model (see Cassandras et al. 2010; Wardi et al. 2010; Yao and Cassandras 2013). As mentioned above, this suggests the potential application of IPA not only in system optimization via off-line simulation, but also in real-time control where the sample paths are generated from the actual system.

Summary and Current Research Directions

This paper narrates the evolution of fundamental ideas underscoring the development of perturbation analysis since its inception in 1979 (Ho et al. 1979). Introduced to solve a specific design-optimization problem in transfer

lines, PA has evolved into a framework for sample-path sensitivity analysis of stochastic hybrid dynamical systems. Its main focus has been on infinitesimal perturbation analysis, which gives gradient estimators of expected-value performance functions that can be naturally used in optimization. During the 1980s and 1990s, the main theoretical problem regarding IPA concerned its unbiasedness and strong consistency, thought to be essential conditions for its effective use in optimization. Various extensions of the basic IPA technique have been developed, including different sample-path representations of a given performance function and alternative approximate-modeling frameworks for DES by SFM and their generalizations to stochastic hybrid systems.

In the past 15 years, the focus of research on PA has shifted to large-scale, complex systems. They include large-scale Markov systems with applications to learning, Markov decision processes, and other complex stochastic optimization problems (e.g., Cao 2007, 2015) and decentralized control and event-based control systems with applications to multi-agent networks and cyber-physical systems (e.g., Zhong and Cassandras 2010; Cassandras et al. 2013). A recent historical survey of PA (Wardi et al. 2018) provides a detailed description of the evolution of the IPA technique and a more-comprehensive exposition of current research directions.

Perturbation Analysis of Steady-State Performance and Relative Optimization

Xi-Ren Cao

Department of Automation, Shanghai Jiao Tong University, Shanghai, China

Institute of Advanced Study, Hong Kong University of Science and Technology, Hong Kong, China

Abstract

We introduce some special theories and methodologies for perturbation analysis (PA) and optimization of steady-state performance and their extensions. Such theories and methodologies utilize the special features of a dynamic systems and usually take different perspectives from the traditional optimization approaches, and therefore they may lead to new insights, new results, and efficient algorithms. The topics discussed include the gradient-based optimization for system with continuous parameters and the direct-comparison-based optimization for systems with discrete policies. Both constitute the relative optimization approach, an alternative to dynamic programming. This approach also applies to continuous-time and continuous-state dynamic systems, leading to a new paradigm of stochastic control.

Introduction

In this entry, we introduce some special theories and methodologies for perturbation analysis (PA) and optimization of steady-state performance and their extensions. Such theories and methodologies utilize the special

features of a dynamic systems and usually take different perspectives from the traditional optimization approaches, and therefore they may lead to new insights, new results, and efficient algorithms. The topics discussed include the gradient-based optimization for system with continuous parameters and the direct-comparison-based optimization for systems with discrete policies. Both constitute the so-called relative optimization approach, an alternative to dynamic programming. This approach also applies to continuous-time and continuous-state dynamic systems, leading to a new paradigm of stochastic control.

As discussed in ▶ “[Perturbation Analysis of Discrete Event Systems](#),” perturbation analysis (PA) can be applied to both finite-period and steady-state performance. This chapter will mainly focus on the latter and a related topic, the relative optimization, which includes the gradient-based optimization for systems with continuous parameters and the comparison-based optimization for systems with discrete parameters or policies.

Gradient-Based Approaches

Basic Ideas

The gradient-based performance optimization of discrete event dynamic systems (DEDSs) consists of three steps:

1. Developing efficient algorithms to estimate the performance gradients using the special features of a DEDS
2. Studying the properties of the gradient estimates, including investigating whether they are unbiased and/or strongly consistent
3. With the gradient estimates, developing efficient optimization algorithms

Steps 1 and 2 are referred to as PA, and Step 3 is usually done together with standard gradient-based optimization approaches, such as hill-climbing type of approaches and stochastic approximation approaches such as the Robbins-Monro algorithm (Robbins and Monro [1951](#)).

Our focus here is on PA for steady-state performance. The main principle for estimating the gradients of steady-state performance is decomposition. In a DEDS, a small change in the value of a system parameter induces a series of changes on the system’s sample path; each of such changes is called a *perturbation*. A single perturbation alone will affect the sample path and therefore affect the system performance. Such an effect is typically small, and therefore, the linear superposition usually holds. Thus, the effect of a small parameter change on the steady-state performance can be determined by summing up the effects of all the perturbations induced (or generated) by the parameter change. This principle is illustrated by Fig. 1, and it applies to many different systems with different performance criteria. Following the principle, efficient algorithms can be developed, and their strong consistency can be proved (Cao [2007](#)). Its application to queueing systems and Markov systems will be discussed in the following two subsections.

Queueing Systems

The gradient-based approach for DEDSs starts with queueing systems, known as infinitesimal perturbation analysis (IPA), or simply PA, ▶ “[Perturbation Analysis of Discrete Event Systems](#).” Queueing systems are widely used as a model for many DEDSs in literature and have very unique structural features, and PA utilizes such special features to develop fast algorithms to estimate the performance gradients.

We first give a brief explanation for the simple rules of PA of queueing systems (Ho and Cao [1983, 1991](#)). Consider a closed Jackson network with M servers and N customers. The service times of customers at server i are exponentially distributed with service rate μ_i , $i = 1, 2, \dots, M$. After a customer completes its service at server i , it goes to server j with a routing probability q_{ij} , $i, j = 1, 2, \dots, M$. The service discipline is first come first served. The number of customers at server i is denoted as n_i , and the system state is denoted as $\mathbf{n} = (n_1, n_2, \dots, n_M)$. The state process is $\mathbf{n}(t) = (n_1(t), n_2(t), \dots, n_M(t))$ with $n_i(t)$ being the number of customers at

Perturbation Analysis of Steady-State Performance and Relative Optimization,
Fig. 1 The decomposition of performance changes

Perturbation Analysis of Steady-State Performance and Relative Optimization,
Fig. 2 Perturbation generation and propagation in a queueing network

server i at time t , $i = 1, 2, \dots, M$, $t \geq 0$. Define T_l as the l th state transition time of the process $\mathbf{n}(t)$.

Figure 2 illustrates an example of a sample path where each stair-style line represents a trajectory of the number of customers at one server, and the customer transitions among servers are indicated by dotted arrows.

An exponentially distributed service time with rate μ can be generated according to $s = -\frac{1}{\mu} \ln \zeta$, where ζ is a uniformly distributed random number in $[0, 1]$. Now let the service rate of a server, say server k , change from μ_k to $\mu_k + \Delta\mu_k$, $\Delta\mu_k < \mu_k$. Then the service time s will change to $s' = -\frac{1}{\mu_k + \Delta\mu_k} \ln \zeta$ (the same ζ is

used for both s and s'). Thus, the perturbation of the service time induced by the change in μ_k is

$$\Delta s = s' - s \approx -\frac{\Delta\mu_k}{\mu_k} s. \quad (1)$$

In summary, because of a small (infinitesimal) change of service rate $\Delta\mu_k$, every customer's service completion time at server k will be delayed by a small amount Δs that is proportional to its original service time with a multiplier $-\frac{\Delta\mu_k}{\mu_k}$; or, we say that server k obtains a perturbation of Δs . This is the rule of *perturbation generation*.

Next, we observe that a perturbation will affect the service starting and completion times of other customers in the same server and in other

servers in the network. We say a perturbation will be *propagated* through the network. First, the perturbations generated at a server will accumulate until this server is idle. When the server enters an idle period, all its perturbations will be lost. (After the idle period, the service starting time is determined by the customer that terminates the idle period, which carries the perturbation of another server.) Second, when a customer finishes its service at server i and enters server j after an idle period of server j , server j will obtain the same amount of perturbations as server i . If server j is not idle at this time, the perturbation at server i will only affect the arrival time of this customer and will not affect any other customers/servers.

Figure 2 illustrates the perturbation generation and propagation process of a network in which the service rate of server 1 is decreased with an infinitesimal amount. Given a system sample path obtained by simulation or observation, we can record the perturbations of all servers as they are generated and propagated along the sample path. From the perturbations, we can get a perturbed sample path and finally get the performance changes caused by the change in the service rate. Specifically, we have the following algorithm for the perturbations of the service completion times (if server k 's service rate is perturbed).

Algorithm 1 Perturbation analysis

1. *Initialization:* Set variables $\Delta_i = 0, i = 1, 2, \dots, M$.
2. *Perturbation generation:* At the l th service completion time of server k , set $\Delta_k = \Delta_k + s_{k,l}, l = 1, 2, \dots$, where $s_{k,l}$ is the service time of the l th customer at server k .
3. *Perturbation propagation:* If a customer from server i terminates an idle period of server j , set $\Delta_j = \Delta_i, i, j = 1, 2, \dots, M$.

In Step 2, we add $s_{k,l}$ as the perturbation generated, instead of $-\frac{\Delta\mu_k}{\mu_k}s_{k,l}$ as indicated by (1). The factor $-\frac{\Delta\mu_k}{\mu_k}$ will be canceled when estimating performance derivatives with respect to $\Delta\mu_k$. The algorithm yields a perturbed sample path. With the original path and the perturbed path, we can estimate the original and perturbed (steady-state) throughput, and then the

estimates of its derivative with respect to μ_k can be obtained, and it is proved that the estimate is strongly consistent. Only a few lines need to be added in the simulation code to obtain the derivatives. Experiments show that the results are very accurate (error is around 5 %, compared with analytical results, Ho and Cao 1983).

Markov Systems

The decomposition principle shown in Fig. 1 has been applied to Markov systems (Cao 2007).

Consider an irreducible and aperiodic Markov chain $\mathbf{X} = \{X_n : n \geq 0\}$ on a finite state space $\mathcal{S} = \{1, 2, \dots, M\}$ with transition probability matrix $P = [p(j|i)]_{i,j=1}^{M,M} \in [0, 1]^{M \times M}$, with $p(j|i)$ being the transition probability from state i to state j . Let $\pi = (\pi_1, \dots, \pi_M)$ be the vector representing its steady-state probabilities and $f = (f_1, f_2, \dots, f_M)^T$ be the reward (or cost) vector, where “ T ” represents transpose. We have $Pe = e$, where $e = (1, 1, \dots, 1)^T$ is an M -dimensional vector whose all components equal 1, and we have $\pi = \pi P$. We consider the long-term average (steady-state) performance defined as

$$\begin{aligned} \eta &= E_\pi(f) = \sum_{i=1}^M \pi_i f_i \\ &= \pi f = \lim_{L \rightarrow \infty} \frac{F_L}{L}, \quad w.p.1, \end{aligned} \quad (2)$$

where

$$F_L = \sum_{l=0}^{L-1} f(X_l).$$

Let P' be another ergodic transition probability matrix on the same state space. Suppose P changes to $P(\delta) = P + \delta Q = \delta P' + (1 - \delta)P$, with $\delta > 0$, $Q = P' - P = [q(j|i)]$, and the reward function f keeps the same. We have $Qe = 0$. The performance measure will change to $\eta(\delta) = \eta + \Delta\eta(\delta)$. The derivative of η in the direction of Q is defined as $\frac{d\eta(\delta)}{d\delta} = \lim_{\delta \rightarrow 0} \frac{\Delta\eta(\delta)}{\delta}$.

In this discrete-state Markov system, a perturbation means that the system is perturbed from one state i to another state j . For example, consider the case where $q(i|k) = \frac{1}{2}, q(j|k) = \frac{1}{2}$, and

$q(l|k) = 0$ for all $l \neq i, j$. Suppose that these probabilities change to $q(i|k) = \frac{1}{2} + \delta$, $q(j|k) = \frac{1}{2} - \delta$, and $q'(l|k) = 0$ for all $l \neq i, j$. Then it may happen that at some time in the original sample path, the system transits from state k to state i , but in the perturbed path, it transits from state k to state j instead. In this case, we say that the change in transition probabilities induces a perturbation from i to j at this time. To study the effect of such a perturbation, we consider two independent sample paths $\mathbf{X} = \{X_n; n \geq 0\}$ and $\mathbf{X}' = \{X'_n; n \geq 0\}$ with $X_0 = i$ and $X'_0 = j$; both of them have the same transition matrix P . The average effect of a perturbation from i to j , $i, j = 1, \dots, M$, on F_L can be measured by the *perturbation realization factor* defined as

$$d(i, j) = \lim_{L \rightarrow \infty} E \left[\sum_{l=0}^{L-1} (f(X'_l) - f(X_l)) | X_0 = i, X'_0 = j \right]. \quad (3)$$

The matrix $D \in \mathcal{R}^{M \times M}$, with $d(i, j)$ as its (i, j) th element, is called a *realization matrix*. From (3), it is easy to prove that D satisfies the equation (Cao 2007)

$$D - PDP^T = F, \quad (4)$$

where $F = fe^T - ef^T$. Because $d(i, j) = -d(j, i)$, for any i, j , and $d(i, k) = d(i, j) + d(j, k)$ for any i, j , and k , we may define a vector $g = (g(1), \dots, g(M))^T$ such that

$$d(i, j) = g(j) - g(i), \quad (5)$$

and $D = ge^T - eg^T$. g is called a *performance potential*, which can be estimated with many sample path-based algorithms, and it satisfies the Poisson equation (Cao 2007)

$$(I - P + e\pi)g = f. \quad (6)$$

Intuitively, (3) and (5) indicate that every visit to state i contributes to F_L on the average by the amount of $g(i)$, so the effect of a perturbation from i to j is $d(i, j) = g(j) - g(i)$. Now, we consider a sample path consisting of L

transitions. Among these transitions, on the average there are $L\pi_i$ transitions at which the system is at state i . After being at state i , the system jumps to state j on the average $L\pi_i p(j|i)$ times. If the transition probability matrix P changes to $P(\delta) = P + \delta Q$, then the change in the number of visits to state j after being at state i is $L\pi_i q(j|i)\delta = L\pi_i [p'(j|i) - p(j|i)]\delta$. This contributes a change of $\{L\pi_i [p'(j|i) - p(j|i)]\delta\}g(i)$ to F_L . Thus, the total change in F_L due to the change of P to $P(\delta)$ is

$$\begin{aligned} \Delta F_L &= \sum_{i,j=1}^M L\pi_i [p'(j|i) - p(j|i)]\delta g(i) \\ &= L(\pi Qg)\delta. \end{aligned}$$

Finally, we have

$$\frac{d\eta}{d\delta} = \lim_{\delta \rightarrow 0} \frac{1}{\delta} \frac{\Delta F_L}{L} = \pi Qg = \pi(P' - P)g. \quad (7)$$

This equation can be easily proved by the Poisson equation (6). The above reasoning gives an intuitive explanation. If the reward function also changes from f to $f(\delta) = f + \delta(f' - f)$, then (7) becomes

$$\frac{d\eta}{d\delta} = \pi[(P'g + f') - (Pg + f)]. \quad (8)$$

Further Works

The ideas described in the previous subsections may stimulate new research topics in theoretical analysis, estimation algorithms, and applications. Here we can only give a very brief review for some of them.

1. There is a large literature on whether the PA-based derivative estimates are unbiased (finite period) and/or strongly consistent (steady state). This was first formulated in Cao (1985) and was further discussed in Heidelberger et al. (1988). By now, there have been extensive studies in this direction: proving the unbiasedness or consistency for various systems and modifying the approach for system when the IPA estimates are not unbiased (e.g., Cassandras and Lafortune

1999; Glasserman 1991; Fu and Hu 1997). This also includes the recently proposed fluid model; see ▶ “[Perturbation Analysis of Discrete Event Systems](#).”

2. Another research topic is how to develop fast and efficient algorithms for estimating the performance gradients, especially in the case of Markov systems; see, e.g., Cao and Wan (1998), Baxter and Bartlett (2001), and Cao (2005). This is called *policy gradients* in the reinforcement learning literature.
3. There are also research works on how the gradient estimates and policy iteration (see section “[Direct Comparison and Policy Iteration](#)”) can be combined with stochastic approximation approaches to develop fast convergent optimization algorithms; see Marbach and Tsitsiklis (2001) for gradient-based approach and Fang and Cao (2004) for policy iteration-based approach.

Direct Comparison and Policy Iteration

The sensitivity-based view has been extended to optimization in discrete spaces of policies. With this view, we can develop a new approach to performance optimization based on a direct comparison of the performance of any two policies. This provides an alternative to the standard dynamic programming to solving the Markov decision processes (MDP) types of problems; it also has been applied to solve some problems when the standard MDP fails (Cao 2007; Cao and Wan 2017).

In an MDP, there is an action space denoted as $\mathcal{A}$. For simplicity, we only consider the discrete case. When the system is at any state $i \in \mathcal{S}$, an action $\alpha = d(i)$ is taken, which controls the system transition probability, denoted as $p^\alpha(j|i)$, $i, j \in \mathcal{S}$, and the reward function, denoted as $f(i, \alpha)$. The mapping $d : \mathcal{S} \rightarrow \mathcal{A}$ is called a *policy*. Since a policy corresponds to a transition probability matrix $P^d = [p^{d(i)}(j|i)]_{i,j=1}^M$ and the reward vector $f^d = (f(1, d(1)), \dots, f(M, d(M)))^T$, we also call the pair (P, f) a policy.

Consider two policies (P, f) and (P', f') , and assume that the Markov chain under both policies is ergodic. We use prime “'” to denote the quantities associated with (P', f') . First, multiplying both sides of the Poisson equation (6) with π' on the left and after some calculations, we get

$$\eta' - \eta = \pi' \{ (P'g + f') - (Pg + f) \}. \quad (9)$$

This is called a *performance difference formula*, and many optimization results can be derived from it in an intuitive way.

Policy Iteration and the Optimality Equation

The difference formula (9) has a nice decomposition structure: it contains two factors, the first one is π' , which does not depend on P , and the second one is $(P'g + f') - (Pg + f)$, in which all the parameters are known except the performance potential g , which can be obtained by only analyzing system with P . This nice feature makes the difference formula the basis of performance optimization.

For two M -dimensional vectors a and b , we define $a = b$ if $a(i) = b(i)$ for all $i = 1, 2, \dots, M$; $a \leq b$ if $a(i) \leq b(i)$ for all $i = 1, 2, \dots, M$; $a < b$ if $a(i) < b(i)$ for all $i = 1, 2, \dots, M$; and $a \leq b$ if $a(i) < b(i)$ for at least one i and $a(j) = b(j)$ for other components. The relation $\leq$ includes $=$, $\leq$, and $<$. Similar definitions are used for the relations $>$, $\geq$, and $\geq$.

Next, we note that $\pi'(i) > 0$ for all $i = 1, 2, \dots, M$. Thus, from (9), we know that if $(P' - P)g + (f' - f) \geq 0$, then $\eta' - \eta > 0$. From (9) and the fact $\pi' > 0$, the proof of the following lemma is straightforward.

Lemma 1 *If $Pg + f \leq (\leq) P'g + f'$, then $\eta < (\leq) \eta'$.*

It is interesting to note that in the lemma, we use only the potentials with one Markov chain, i.e., g . Thus, because of the special structure of the performance difference formula (9), if the condition in Lemma 1 holds, to compare the performance measures under two policies, we may only need the potentials with one policy.

Policy iteration and the optimality equation can be easily derived from (9) and Lemma 1. A

policy iteration algorithm is illustrated in Algorithm 2.

Algorithm 2 Policy iteration

1. Guess an initial policy d_0 , and set $k = 0$.
2. (Policy evaluation) Obtain the potential g^{d_k} by solving the Poisson equation $(I - P^{d_k})g^{d_k} + \eta^{d_k}e = f^{d_k}$ or estimating it on a sample path. (The superscript “ d_k ” is added to quantities associated with policy d_k .)
3. (Policy improvement) Choose

$$d_{k+1} \in \arg \left\{ \max_{d \in \mathcal{D}} [f^d + P^d g^{d_k}] \right\}, \quad (10)$$

component-wise (i.e., to determine an action for each state). If in state i , action $d_k(i)$ attains the maximum, and set $d_{k+1}(i) = d_k(i)$.

4. If $d_{k+1} = d_k$, stop; otherwise, set $k := k + 1$ and go to Step 2.
-

It follows directly from Lemma 1 that when the iteration does not stop, the performance improves at each iteration. It can be proved easily by construction that the iteration stops at an optimal policy. Again, from Lemma 1, when the iteration stops at a policy $\hat{d}$, it holds

$$\eta^{\hat{d}}e + g^{\hat{d}} = \max_{d \in \mathcal{D}} \{f^d + P^d g^{\hat{d}}\}. \quad (11)$$

This is the Hamilton-Jacobi-Bellman (HJB) optimality equation. If we further define the Q-factor,

$$Q^d(i, \alpha) = f(i, \alpha) + \sum_j p^\alpha(j|i)g^d(j). \quad (12)$$

Then the policy iteration equation (10) and the HJB equation (11) become

$$d_{k+1}(i) := \arg \max_{\alpha \in \mathcal{A}} \{Q^{d_k}(i, \alpha)\} \quad (13)$$

and

$$Q^{\hat{d}}(i, \alpha) = \max_{\beta \in \mathcal{A}} \{Q^{\hat{d}}(i, \beta)\}, \quad \alpha = \hat{d}(i). \quad (14)$$

The only difference between (8) and (9) is that π in (8) is replaced by π' in (9). This leads to an interesting observation: *policy iteration in*

MDPs in fact chooses the policy with the steepest directional derivative as the policy in the next iteration. Therefore, policy iteration in fact can be viewed as the “gradient-based” optimization in a discrete space.

In our approach, the HJB equation and policy iteration are obtained from the performance difference equation (9), which compares the performance of any two policies. It is hence called a *direct-comparison*-based approach, which, together with the gradient-based approach, constitutes the *relative optimization* approach. This approach also applies to more general problems, such as multichain Markov systems, systems with absorbing states, and problems with other performance criteria such as the discounted performance and the bias, etc.

The relative optimization approach has been successfully applied to the n th-bias optimality problem (Cao 2007). Essentially, starting with the performance difference formulas (those similar to (9) for different performance), we can develop a simple and direct approach to derive the results that are equivalent to the sensitive discount optimality for multichain Markov systems with long-run average criteria (Puterman 1994), and no discounting is needed and no dynamic programming is used. The approach, motivated by the development for discrete event dynamic systems, provides a clear overall picture for the area of MDP.

The relative optimization approach also applies to performance optimization of dynamic systems with continuous-time and continuous-states and hence provides a new framework to stochastic control and leads to some new results. The approach can also be applied to some problems where dynamic programming fails, including the event-based optimization problems, where the sequence of events may not be Markovian; see the next two sections.

Event-Based Optimization

It is well-known that for most systems modeled by Markov processes, the state spaces are too large, and it is not computationally feasible

to implement policy iteration or to solve the HJB equations. On the other hand, in many practical problems in engineering, finance, and social sciences, control actions are only taken when certain events occur. For example, in traffic control of a network of subnetworks, oftentimes one cannot control the traffic in the same subnetwork, and control actions are only applied when there are packets transferring among different subnetworks. In a portfolio management problem, the investor sells or buys stocks when the price history experiences some predetermined patterns (e.g., reaches some level). In a sensor network, actions are taken only when one of the sensors detects some abnormal situations. In a material handling problem, actions are taken when the inventory level falls below certain threshold.

Conceptually, anything happened in the past can be chosen as an event. However, the number of such events is too big (much bigger than the number of states), and studying all these events makes analysis infeasible and defeats our original purpose. Therefore, to properly define events, we need to strike a balance between the generality on the one hand and the applicability on the other hand.

In the event-based setting, an event e is defined as a set of state transitions with certain common properties. That is, $e := \{(i, j) : i, j \in \mathcal{S} \text{ and } \langle i, j \rangle \text{ has common properties}\}$, where $\langle i, j \rangle$ denotes a state transition from i to j . This definition can also be easily generalized to represent a finite sequence of state transitions. We shall see that in many real problems, the number of events requiring control actions is usually much smaller than that of the states.

An event-based policy d is defined as a mapping from $\mathcal{E}$ to $\mathcal{A}$, with $\mathcal{E}$ being the space of all events. That is, $d : \mathcal{E} \rightarrow \mathcal{A}$. When an event $e \in \mathcal{E}$ happens, we choose an action $a = d(e)$ according to a policy d . Let $\mathcal{D}_e$ denote the set of all the stationary and deterministic event-based policies. The reward function under policy d is denoted as $f^d = f(i, d(e))$, and the associated long-run average performance is denoted as η^d . Our goal is to find an optimal policy $\hat{d}$ which maximizes the long-run average performance as follows:

$$\hat{d} = \arg \max_{d \in \mathcal{D}_e} \left\{ \eta^d \right\} \quad (15)$$

The main difficulty in developing the event-based optimization theories and algorithms lies in the fact that the sequence of events is usually not Markovian. The standard optimization approach such as dynamic programming does not apply to such problems. However, we can apply the relative optimization approach to this event-based optimization problem. Here we give a very brief discussion (Cao 2007; Xia et al. 2014).

Consider an event-based policy d , $d \in \mathcal{D}_e$. When event e occurs, the conditional transition probability is denoted as $p^{d(e)}(j|i, e)$. Let $\pi^d(i|e)$ be the conditional steady-state probability of state i when event e occurs under policy d . Define the aggregated Q-factor

$$Q^d(e, \alpha) = \sum_i \pi^d(i|e) \times \left[f(i, \alpha) + \sum_j p^\alpha(j|i, e) g^d(j) \right]. \quad (16)$$

We may use these aggregated Q-factors to develop an event-based policy iteration algorithms as Algorithm 2 and obtain the policy iteration equation (cf. (13))

$$d_{k+1}(e) := \arg \max_{\alpha \in \mathcal{A}} \{ Q^{d_k}(e, \alpha) \}, \quad e \in \mathcal{E}, \quad (17)$$

and the event-based HJB optimality equation (cf. (14)) is

$$Q^{\hat{d}}(e, \alpha) = \max_{\beta \in \mathcal{A}} \{ Q^{\hat{d}}(e, \beta) \}, \quad \alpha = \hat{d}(e). \quad (18)$$

It can be proved that if the conditional probability $\pi^h(i|e)$ does not depend on the policy, i.e.,

$$\pi^h(i|e) = \pi^d(i|e), \quad \forall i, e, \quad \text{and } h, d, \quad (19)$$

then policy iteration (17) indeed leads to a sequence of increasing performance and (18) specifies an event-based optimal policy.

The event-based aggregated Q-factor (16) can be estimated on a sample path in the same way as for potentials (Cao 2007; Xia et al. 2014). The number of events requiring actions is usually

much smaller than the number of states, and in some cases such as the network admission control problem, it is linear to the system size.

The crucial condition for the above event-based optimization is (19). There are many problems, such as the control of the networks of networks and the portfolio management problem, for which the condition holds; there are also many problems for which the condition does not hold. The error in applying (18) and policy iteration (17) comes from the difference between $\pi^h(i|e)$ and $\pi^d(i|e)$ at each iteration. Further research is needed.

We use a computer network as an example, in which each computer or router can be modeled as a queueing subnetwork and the computer network is then a network of such subnetworks. Assume that there are M subnetworks, and subnetwork m , $m = 1, 2, \dots, M$, consists of k_m servers. The number of customers at the j th server of subnetwork m is denoted as $n_{m,j}$, $j = 1, 2, \dots, k_m$, and the number of customers in all the servers in subnetwork m is denoted as $N_m = \sum_{j=1}^{k_m} n_{m,j}$. Suppose the service time is exponentially distributed, then the system state is $\mathbf{n} := (n_{1,1}, \dots, n_{1,k_1}; \dots; n_{M,1}, \dots, n_{M,k_M})$, and define the aggregated state as $\mathbf{N} := (N_1, \dots, N_M)$. Suppose that the transition probabilities among the servers in the same subnetwork are fixed and we can only control the transition probabilities among the subnetworks, and furthermore, we can only observe $\mathbf{N}$. Then the problem can be modeled as an event-based optimization with an event being a customer transition among subnetworks, and meanwhile, the aggregated state is $\mathbf{N}$. It can be proved that the condition (19) holds, and therefore, we may apply policy iteration (17) and HJB equation (18) (Xia et al. 2014).

Many existing problems fit the event-based framework. For example, in a partially observable Markov decision process (POMDP), we may define an observation, or a sequence of observations, as an event. Other examples include state and time aggregations, hierarchical control (hybrid systems), and options. Different events can be defined to capture the special features in these different problems. In this sense, the

event-based approach may provide a unified view to these different problems (Cao 2007; Xia et al. 2014).

The Relative Optimization Approach, Stochastic Control, and Others

We refer to the approaches discussed in the previous sections the *relative optimization* approach. The name comes from the fact that only the relative values of the performance measures are used in optimization. When the parameters are continuous, it is the gradient-based approach, and the focus is on developing efficient algorithms that utilize the particular system structure to estimate the gradients (to justify the algorithms, the unbiasedness or the consistency of the estimates should be considered). When the parameters are discrete, it is the direct-comparison approach that leads to policy iteration and the HJB equations, and policy iteration can be viewed as the gradient-based method in discrete spaces. This approach is different from the conventional dynamic programming, and it has been successfully applied to MDP with different criteria, the n -bias optimization problems, and time nonhomogeneous Markov chains (Cao 2015) and some other problems that dynamic programming may not work well.

The relative optimization approach was motivated by the study of discrete event dynamic systems (DEDS). It has been realized that the principles and methodologies developed for DEDSs also apply to the optimization of continuous-time and continuous-state (CTCS) systems, and therefore, the approach provides to a new framework for the area of stochastic control, and some new results can be obtained.

In CTCS systems, the dynamic is driven by Brownian motions or Levy processes. A typical CTCS Markov process is the Ito diffusion process defined by the stochastic differential equation. The transition probability matrix in a DEDS should be replaced by the infinitesimal generator in a CTCS system, which is an operator on the space of continuous functions. With the perfor-

mance difference formulas, we can redevelop the stochastic optimal control theory for many performance measures, including the long-run average, discounted performance, and finite horizon problems, with no dynamic programming. In addition, new results can be obtained. For example, explicit optimality conditions can be derived at non-smooth points of a value function, and viscosity solution to the HJB equation is not needed; multi-class CTCS processes can be defined, and optimality conditions can be derived for such processes. See Cao (2017, 2019) for more details.

Other applications of the relative optimization approach include the *time-inconsistent optimization problems*. In behavioral finance, people's preference is modeled with a distorted probability. For example, a risk-taking person buys lotteries, because in her/his mind, she/he enlarges the possibility of winning a large sum, and a risk-averse person buys insurance, because she/he is afraid of a big loss and therefore enlarges its probability.

The optimization problem with a distorted probability suffers from the time-inconsistent issue; i.e., an optimal policy for the problem in period $[t, T)$, $0 < t < T$, is not optimal in the same period for the problem in $[0, T]$. Thus, the standard dynamic programming fails.

The gradient-based approach has been applied to the portfolio management problem with probability distortion. With this approach, we discovered that the performance with distorted probability maintains some sort of linearity called *monolinearity*. This property shed new insights to the portfolio management problem and the nonlinear expected utility theory (Cao and Wan 2017).

Conclusion

The relative optimization approach has been developed to the performance optimization of both DEDSs and CTCS systems. The approach utilizes the dynamic structure of a system. For systems with continuous parameters, it is the gradient-based optimization, in which the special feature of the system helps in developing

efficient algorithms to estimate the performance derivatives; for systems with discrete policies, it is the direct-comparison-based approach, with which policy iteration and HJB equations can be derived intuitively by using the performance difference formulas. Policy iteration can be viewed as the gradient method in a discrete space. The estimation of gradients and the implementation of policy iteration can be carried out on a given sample path, and efficient online learning algorithms can be developed (Cao 2007). The approach provides an alternative to the traditional dynamic programming and therefore can be applied to some problems where dynamic programming does not work.

can physically interact with humans to collaborate with them in the execution of several tasks in different application domains, from manufacturing to healthcare, from inspection to maintenance. This chapter reviews all such technologies, which range from innovative actuation systems, such as series elastic actuators or highly integrated torque controlled joints, to sensing systems, such as joint torque sensors and force/tactile devices or 3D vision systems for tracking of humans acting in the robot workspace. Another major technological advancement that enabled safe physical human-robot interaction (pHRI) is the compliance control of robotic manipulators in conjunction with smart collision detection and reaction strategies to be adopted in case of accidental human-robot contacts. Programming of robots that are allowed to physically interact with humans is by far more intuitive than standard programming procedures and, again, this is enabled by smart technologies like haptic gestures recognition in combination with advanced torque control or tactile skin devices.

Abstract

Robots and humans can nowadays share their workspace safely. This possibility has been enabled by a combination of technologies leading to the so-called cobots, robots that

Introduction

Robots have been conceived since the dawn of robotics as machines capable of physical interaction with the environment. They are designed to respond to external stimuli, with different autonomy levels, just as a computer or a mobile phone does, but with a great difference: they are capable to physically change the world they are interacting with by exchanging mechanical energy. First industrial robots were designed to interact only with unanimated objects mainly to perform only repetitive tasks, and they were not allowed to interact with humans, because of severe safety requirements.

Nowadays, many robots are designed to perform their task not only on the shop floor of a manufacturing industry but also in scenarios where they have to share their workspace with humans, e.g., in service or personal robotics applications. This new generation of robots are called *cobots*, that stands for *collaborative robots*, since they are specifically designed to assist humans during task execution through direct physical interaction.

The cobot technology is a real breakthrough in robotics, and to achieve such result, engineers had to face a number of challenges from many points of view in the development process, from mechanical design and actuation to sensing and control architectures. The primary objective they had to pursue is the safety of such products during the physical interaction with human operators, both in case of intentional and unintentional contacts.

Figure 1 lists the main requirements that should be satisfied and the most relevant design objectives of the mechanical design, actuation and sensing system, as well as control architecture of a cobot. Most modern commercial cobots (some of them are depicted in Fig.2) adopt lightweight materials, and their links have smooth shapes without any sharp edge. The joint actuators have an intrinsic compliance or can be controlled in such a way to exhibit a programmable compliance. Usually, apart from the standard joint position sensors, these arms are endowed with redundant sensors and with joint torque sensors. Availability of direct

torque measurements to the control system enables advanced features such as programmable compliant motion (impedance control, force control) that, on one hand, increases the safety level during the interaction with human operators and, on the other hand, allows the robot to adapt to external uncertain contact constraints. All cobots give the user the possibility to program the robot by using hand guidance, usually through the aid of a smart human-machine interface (HMI) on board of the last link of the arm or even through haptic gestures that can be recognized based on external contact estimation. Reliable detection of contact with the environment and, most importantly, with the human operator is of paramount importance. The ability to distinguish between intentional contact and accidental collisions is also a distinguishing feature of some cobots. As better explained in the section dedicated to sensing systems, the detection can be based either on direct measurement of external forces or through model-based estimation algorithms.

Human-Robot Interaction Technology

Design of robots that are allowed to physically interact with humans in a safe manner is characterized by different approaches which involve design of actuation, sensing, and control subsystems of the robot.

Actuation System

To satisfy the design requirements of a cobot discussed in Fig. 1, e.g., the lightweight design and compliant behavior, distinct approaches are generally adopted for the actuation system, i.e., the *mechatronic approach*, the *tendon-driven approach*, and the *intrinsically flexible approach*.

In the mechatronic approach, power and control electronics is integrated into the joints to achieve high modularity so as to obtain different kinematic designs while maintaining joint characteristics. Joint modules are usually based on high-torque motors with high transmission ratios in combination with joint torque sensors to get accurate joint torque tracking capabilities, besides classical joint position sensing. Compliance is then ensured by proper control algorithms (see “[Control System](#)” section).

Dually, tendon-driven robots are typically actuated by remote actuators (usually placed in the robot base) with the aim to reduce the moving inertia and in turn to limit the mechanical energy of any possible collision during the robot motion. Low reduction ratios are usually adopted in the

tendon mechanisms so as to obtain backdrivable systems.

Another method to achieve high dynamic performances, still ensuring safety (including that of the robot) in case of collisions, consists in the adoption of intrinsically compliant mechanisms in the robot joints. This is the case of the well-known series elastic actuator (SEA) technology mostly adopted to actuate robot legs or powered orthoses. The main SEA characteristics are their intrinsic resistance to impacts and vibrations and the low output mechanical impedance, which makes them backdrivable. However, their impedance is fixed, while it might be useful, depending on the application, to have actuators with adjustable impedance or at least compliance. Variable Stiffness Actuators (VSA) and Variable Impedance Actuators (VIA) were originally conceived to make robots safer during unforeseen collisions by dynamic decoupling of the motor inertia from the link-side inertia, but then they have been adopted to improve robot performance as well depending on the type of task being carried out, e.g., pure positioning (high stiffness) or physical contact (low stiffness). An additional

advantage of actuators including elastic elements is the possibility to store mechanical energy that can be suitably output to the load to improve dynamic performance.

Few examples of all discussed joint actuation technologies are reported in Fig. 3.

Sensing System

The perception system of cobots is usually more rich than the one of a standard robot, for two main reasons. Both implementation of a compliant behavior and detection and reaction to collisions with the environment require sensing systems able to get contact information of the robot with external agents. In standard industrial robots, compliant motion is usually achieved by resorting to wrist force/torque sensors, which are able to measure the contact wrench applied by the end effector to the environment. However, physical interaction of the robot with a human operator, both deliberate and accidental, can take place on every part of the robot body. To this aim, joint torque sensors can be adopted to estimate external forces applied to any link of the robot body. Torque sensing is usually done via strain gauge-based devices and their measurement is used also to implement low-level torque control with a high degree of accuracy, mainly to reject torque disturbances such as friction in gear boxes. Of course joint torque measurements include not only contribution of the external contact forces but also dynamic effects such as gravity, which need to be compensated for. A number of algorithms have been proposed in the literature to solve this problem. The most common approach is the so-called angular momentum-based observer. The most commonly adopted dynamic model of a robot manipulator with flexible joints is the so-called Spong's model, i.e.,

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) = \boldsymbol{\tau} + \boldsymbol{\tau}_{\text{ext}} \quad (1)$$

$$\mathbf{B}\ddot{\boldsymbol{\theta}} + \boldsymbol{\tau} = \boldsymbol{\tau}_m - \boldsymbol{\tau}_F \quad (2)$$

$$\boldsymbol{\tau} = \mathbf{K}_j(\boldsymbol{\theta} - \mathbf{q}) \quad (3)$$

where $\mathbf{q}$ and $\boldsymbol{\theta}$ are the joint position vectors at link and motor sides, respectively, $\mathbf{M}(\mathbf{q})$ is the inertia matrix of the rigid body dynamics, $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$ is the

matrix of Coriolis and centrifugal terms, $\mathbf{g}(\mathbf{q})$ is the vector of gravitational torques, $\boldsymbol{\tau}$ is the vector of joint torques, $\boldsymbol{\tau}_{\text{ext}}$ is the vector of external torques (those corresponding to external contact forces applied to the links), $\mathbf{B}$ is the inertia matrix of the joint motors, $\boldsymbol{\tau}_m$ is the vector of motor driving torques, $\boldsymbol{\tau}_F$ is the vector of friction torques on the motor side, and, finally, $\mathbf{K}_j$ is the joint stiffness matrix.

The model-based observer is based on the equation governing the estimate $\hat{\mathbf{p}}$ of the angular momentum vector $\mathbf{p} = \mathbf{M}(\mathbf{q})\dot{\mathbf{q}}$, namely

$$\dot{\hat{\mathbf{p}}} = -k_O(\hat{\mathbf{p}} - \mathbf{p}) + \boldsymbol{\tau} - \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} - \mathbf{g}(\mathbf{q}) - \dot{\mathbf{M}}(\mathbf{q})\dot{\mathbf{q}}. \quad (4)$$

It is straightforward to verify that the residual $\mathbf{r} = \hat{\mathbf{p}} - \mathbf{p}$ asymptotically converges to the external torque $\boldsymbol{\tau}_{\text{ext}}$ with a time constant proportional to $1/k_O$. Such observer requires full-state feedback as well as joint torque measurements, and it is more suitable to be adopted when the arm is used under impedance or compliance control. Whereas, in case the arm is position controlled, the joint position can be considered very close to the reference $\mathbf{q}_d$, and thus a computationally less expensive algorithm can be used to estimate external joint torques, i.e.,

$$\boldsymbol{\tau}_{\text{ext}} \simeq \boldsymbol{\tau} - \left(\mathbf{M}(\mathbf{q}_d)\ddot{\mathbf{q}}_d + \mathbf{C}(\mathbf{q}_d, \dot{\mathbf{q}}_d)\dot{\mathbf{q}}_d + \mathbf{g}(\mathbf{q}_d) \right). \quad (5)$$

Note how this method is affected only by the noise on the measured joint torque, while algorithm (4) requires differentiation of joint position measurements.

Both the methods discussed above require accurate knowledge of the dynamic model of the robot; moreover, they can be used to detect the components of the contact forces applied to the links and the corresponding contact points only in special cases. On the other hand, direct measurement of contact location and external forces applied to the robot body can be achieved by proper distributed sensing devices, like artificial tactile skins. Most existing tactile skins are able to detect only the contact point and the normal pressure on it, while only few prototypes are able to perform measurement of the complete

Physical Human-Robot Interaction, Fig. 3 (continued)

contact force vector in multiple points. The most adopted technologies are piezoresistive, capacitive, and optoelectronic ones. Some prototypes are reported in Fig. 4 together with joint torque sensors, wrist force sensors, as well as depth cameras used to monitor robot workspace.

In fact, great relevance is taken on by visual perception systems adopted to monitor the robot workspace with the aim to ensure safety of humans that share their workspace with the robot. A real breakthrough in robotics happened at the arrival on the market of low-cost depth cameras, while high-end stereo vision has become widespread only after the adoption of computationally powerful devices such as GPUs (Graphical Processing Units). These perception systems are nowadays capable of accurate tracking of human bodies even in presence of partial occlusions.

Control System

Physical interaction of a robot with the environment, including humans, is certainly more safe when the robot is controlled with a suitable compliance control algorithm. In this way the arm configuration tries to adapt to contact forces rather than following the programmed path as close as possible despite any contact. During the decades, basic compliance control schemes of the early 1980s evolved to more sophisticated algorithms that not only provide the robot with suitable programmable compliant behaviors but also optimize robot configuration to minimize the *effective mass* at the contact point, i.e., the equivalent inertia in the direction of the contact, by resorting to multitask with priority compliance control algorithms. Of course, multiple objectives can be achieved only if the robot has enough degrees of freedom to exploit.

Collision Reaction

During operation of a cobot, an algorithm to detect collisions is always active, and it usefully exploits the external torque estimated as described in the previous section. By comparing the components of the residual $\mathbf{r}$ with suitably selected thresholds (e.g., 10% of the maximum torque of each joint), a collision reaction algorithm is triggered. Different strategies can be adopted, i.e.:

1. the robot is *stopped* at the position reached at the time of collision;
2. the robot control is switched to *gravity compensation mode* so as to obtain a very compliant behavior, i.e., $\boldsymbol{\tau} = \mathbf{g}(\mathbf{q})$;
3. the robot control is switched to the so-called torque reflex mode, i.e., $\boldsymbol{\tau} = \mathbf{g}(\mathbf{q}) + (\mathbf{I} - \mathbf{K}_r)\boldsymbol{\tau}_{\text{ext}}$, such that the robot inertia is scaled by $\mathbf{K}_r^{-1}$;
4. the robot control is switched to *admittance control mode* so as to move the contact point in the direction of the estimated contact force vector but away from the collision area.

In the last case, availability of direct contact force measurements is very useful and safe to ensure a behavior of the robot not influenced by modeling errors but only by sensor noise.

Manual Guidance

One of the features that distinguishes a cobot from a standard industrial robot is the possibility to program the motion of the machine by using the so-called manual guidance or walk-through programming. The basic approach is to control the robot in gravity compensation mode so that it is fully compliant along all directions and the user can manually adjust any link in the desired configuration. Another approach is to use admittance control by measuring the contact force and translating such force into a velocity to move

the arm, e.g., through tactile skins, which can be used also as HMI. If the arm is redundant, redundancy can be exploited in combination with online adaptation of admittance parameters with the aim to enhance the comfort perceived by humans during manual guidance.

Summary and Future Directions

Even though the cobot technology originally imagined by researcher in the late 1990s can now be considered a reality, still a lot of research is being done toward even more powerful and safe robots.

An interesting area of research concerns the combination of compliance control strategies with machine learning methods with the aim to automatically find the right parametrization of compliance controllers for service robotics applications (Leidner et al. 2016) or cognitive reasoning for compliant manipulation (Leidner 2019).

Another research trend is the one toward the investigation of methods to estimate human intention in collaborative workspaces

through human motion prediction (Mainprice and Berenson 2013) as well as human action prediction (Hawkins et al. 2013), e.g., in assembly collaborative tasks in the automotive industry (Kinugawa et al. 2017).

Thinking of human-robot teams carrying out common collaborative tasks is nowadays no longer a dream; recent studies on mutual adaptation explore methods to allow robots to adapt their behavior with the aim to improve the performance of the human-robot team (Nikolaidis et al. 2017).

Recommended Reading

Many surveys can be found in the literature summarizing the main technical achievements that led to the cobot technology (Haddadin and

Croft 2016; Villani et al. 2018; Bauer et al. 2008; Goodrich and Schultz 2007). The first patent citing the term cobot is Colgate and Peshkin (1999). One of the first road maps for the cobot technology development is De Santis et al. (2008), which introduced suggestions to draft metrics for evaluating safety and dependability in pHRI. Those suggestions became the scientific basis of the technical specification ISO/TS 15066 (ISO/TC 299 Robotics 2016), still under review, to be included in the standard ISO 10128 (ISO/TC 299 Robotics 2011).

Literature on actuators suitably designed for pHRI is vast, the integrated joint technology of DLR (Hirzinger et al. 2002) was the basis of more than a commercial cobot, and SEA were first introduced by Pratt et al. (1997) and were later combined with magneto-rheological fluids for controlling the damping of a locomotion system in Garcia et al. (2011). VSA of the David robot was presented in Wolf et al. (2011), while the cable-driven actuation system of the WAM arm appeared in Gordon and Townsend (1989).

Force/tactile sensing systems are nowadays among the hot topics in many robotics conferences as they are the primary source of information on the physical interaction of a robot with its environment. Joint torque sensors of DLR (Hirzinger et al. 2003) are the basis of the mechatronics approach to perform torque control of modern cobots. A number of tactile skins have been developed throughout the years, and the one equipping the iCub in Fig. 4 was first presented in Cannata et al. (2008), while the only artificial skin sensitive to both normal and shear loads is the one presented in Cirillo et al. (2014) and later used in Cirillo et al. (2016) for admittance control and in Cirillo et al. (2017) for manual guidance and intuitive programming via haptic gestures. The manual guidance based on adaptive impedance control was instead proposed in Ficuciello et al. (2015).

Control design of robots with dynamic characteristics typical of a cobot is mostly based on the famous dynamic model of robots with elastic joints proposed by Spong (1987). Such model is at the base of compliance and impedance control algorithms

of lightweight robots (Albu-Schäffer et al. 2007). The same research group has also contributed to the study of hierarchical multitask control algorithms for service robots (Dietrich et al. 2017, 2018), mainly based on the dynamically consistent approach of Featherstone and Khatib (1997) and Sentis and Khatib (2005).

The model-based estimation algorithms for collision detection and reaction based on the generalized momentum date back to De Luca et al. (2006) and Haddadin et al. (2008), but the reader interested in examining in depth the topic can start from the recent survey (Haddadin et al. 2017).

Abstract

Since their introduction in industry a century ago, proportional–integral–derivative (PID) controllers have become the de facto standard for the process industry. In this entry, fundamentals of PID control are outlined, starting from the basic control law. Additional functionalities and the tuning and automatic tuning of the parameters are then considered.

Anti-windup · Autotuning · Controller tuning · Derivative action · PI control · Proportional control · Proportional-integral-derivative control · Ziegler-Nichols

Synonyms

Proportional-Integral-Derivative Control

Introduction

A proportional–integral–derivative (PID) controller is a three-term controller that has a long history in the automatic control field, starting from the beginning of the last century. Owing to its intuitiveness and relative simplicity, in addition to the satisfactory performance that it is able to provide with a wide range of processes, it has become the de facto standard controller in industry. It has been evolving along with the progress of technology, and nowadays it is very often implemented in digital form rather than with pneumatic or electrical components. It can be found in virtually all kinds of control equipments, either as a stand-alone (single-station) controller or as a functional block in Programmable Logic Controllers (PLCs) and Distributed Control Systems (DCSs). Actually, the new potentialities offered by the development of the digital technology and of the software packages have led to a significant growth of the research in the PID control field: new effective tools have been devised for the improvement of the analysis and design methods of the basic algorithm as well as for the improvement of the additional functionalities that are implemented with the basic algorithm in order to increase its performance and its ease of use.

The success of the PID controllers is also enhanced by the fact that they often represent the fundamental component for more sophisticated control schemes that can be implemented when the basic control law is not sufficient to achieve the required performance or when a more complicated control task is of concern.

Basics

Using a PID controller means applying a feedback controller that consists of the sum of three types of control actions: a proportional action, an integral action, and a derivative action.

The proportional control action is proportional to the current control error, according to the expression

$$u(t) = K_p e(t) = K_p (r(t) - y(t)), \quad (1)$$

where u is the controller output, K_p is the proportional gain, r is the reference signal, and y is the process output. Its meaning is straightforward, since it implements the typical operation of increasing the control variable when the control error is large (with appropriate sign). The transfer function of a proportional controller can be trivially derived as

$$C(s) = K_p. \quad (2)$$

The main drawback of using a pure proportional controller is that, in general, it cannot set to zero the steady-state error. This motivates the addition of a bias (or reset) term u_b , namely,

$$u(t) = K_p e(t) + u_b. \quad (3)$$

The value of u_b can then be adjusted manually until the steady-state error is reduced to zero.

In commercial products, the proportional gain is often replaced by the proportional band PB , which is the range of error that causes a full-range change of the control variable, i.e.,

$$PB = \frac{100}{K_p}. \quad (4)$$

The integral action is proportional to the integral of the control error, i.e.,

$$u(t) = K_i \int_0^t e(\tau) d\tau, \quad (5)$$

where K_i is the integral gain. It appears that the integral action is related to the past values of the control error. The corresponding transfer

function is

$$C(s) = \frac{K_i}{s}. \quad (6)$$

The presence of an integral action allows to reduce the steady-state error to zero when a step reference signal is applied or a step load disturbance occurs. In other words, the integral action is able to set automatically the correct value of u_b in (3) so that the steady-state error is zero. For this reason, the integral action is also often called *automatic reset*.

While the proportional action is based on the current value of the control error and the integral action is based on the past values of the control error, the derivative action is based on the predicted future values of the control error. An ideal derivative control law can be expressed as

$$u(t) = K_d \frac{de(t)}{dt}, \quad (7)$$

where K_d is the derivative gain. The corresponding controller transfer function is

$$C(s) = K_d s. \quad (8)$$

The meaning of the derivative action can be better understood by considering the first two terms of the Taylor series expansion of the control error at time T_d ahead:

$$e(t + T_d) \simeq e(t) + T_d \frac{de(t)}{dt}. \quad (9)$$

If a control law proportional to this expression is considered, i.e.,

$$u(t) = K_p \left(e(t) + T_d \frac{de(t)}{dt} \right), \quad (10)$$

this naturally results in a PD controller. The control variable at time t is therefore based on the predicted value of the control error at time $t + T_d$. For this reason, the derivative action is also called *anticipatory control*, or *rate action*, or *pre-act*.

The combination of the proportional, integral, and derivative actions can be done in different ways. In the so-called *ideal* or *non-interacting* form, the PID controller is described by the

following transfer function:

$$C_i(s) = K_p \left(1 + \frac{1}{T_i s} + T_d s \right), \quad (11)$$

where K_p is the proportional gain, T_i is the integral time constant, and T_d is the derivative time constant. An alternative representation is the *series* or *interacting* form:

$$\begin{aligned} C_s(s) &= K'_p \left(1 + \frac{1}{T'_i s} \right) (T'_d s + 1) \\ &= K'_p \left(\frac{T'_i s + 1}{T'_i s} \right) (T'_d s + 1), \end{aligned} \quad (12)$$

where the fact that a modification of the value of the derivative time constant T'_d affects also the proportional action justifies the nomenclature adopted. Suitable conversion formulae can be applied to obtain an ideal PID controller equivalent to a series one. Obtaining an equivalent PID controller in series form starting from an ideal one is possible only if the zeros of the ideal PID controller are real.

Additional Functionalities

The expression (11) or (12) of a PID controller is actually not employed in practical cases because of a few problems that can be solved with suitable modifications of the basic control law.

Modifications of the Derivative Action

From Expressions (11) and (12), it appears that the controller transfer function is not proper, because of the derivative action, and therefore, it cannot be implemented in practice. Indeed, the high-frequency gain of the pure derivative action is responsible for the amplification of the measurement noise in the manipulated variable. This problem can be solved by filtering the derivative action with (at least) a first-order low-pass filter. The filter time constant should be selected in order to suitably filter the noise and to avoid a significant influence on the dominant dynamics of the PID controller. Thus, it can be selected

as T_d/N , where N generally assumes a value between 1 and 33, although in the majority of the practical cases its setting falls between 8 and 16. Alternatively, the overall control variable can be filtered.

Another issue related to the derivative action that has to be considered is the so-called derivative kick. In fact, when an abrupt (stepwise) change of the set-point signal occurs, the derivative action is very large, and this results in a spike in the control variable signal, which is undesirable. This problem could be simply avoided by applying the derivative term to the process output only instead of the control error. In this case, the ideal (not filtered) derivative action becomes

$$u(t) = -K_p T_d \frac{dy(t)}{dt}. \quad (13)$$

Obviously, when the set-point signal is constant, applying the derivative term to the control error or to the process variable is equivalent. Thus, the load disturbance rejection performance is the same in both cases.

Set-Point Weighting for Proportional Action

A typical problem with the design of a feedback controller is to achieve a high performance both in the set-point following task and in the load disturbance rejection task at the same time. For example, for stable processes, a fast load disturbance rejection is achieved with a high-gain (aggressive) controller, which gives an oscillatory set-point step response on the other side. This problem can be approached by using a two-degree-of-freedom control architecture, where a feedback controller is designed to achieve a high bandwidth and therefore a satisfactory load disturbance rejection performance, and then the set-point signal is filtered before applying it to the closed-loop system.

In the context of PID control, this can be achieved by weighting the set-point signal for the proportional action, that is, to define the proportional action as follows:

$$u(t) = K_p(\beta r(t) - y(t)), \quad (14)$$

where the value of β is between 0 and 1.

In this way, the control scheme has a feedback controller (11), and the set-point signal is filtered by the system

$$F(s) = \frac{1 + \beta T_i s + T_i T_d s^2}{1 + T_i s + T_i T_d s^2}. \quad (15)$$

The load disturbance rejection task is decoupled from the set-point following task, and obviously it does not depend on the weight β , which can be employed to smooth the (step) set-point signal in order to damp the response to a set-point change. The smaller the value of β , the smaller the overshoot and the higher the rise time.

Anti-windup

One of the most well-known possible sources of performance degradation is the so-called integrator windup phenomenon, which occurs when the controller output saturates (typically when a large set-point change occurs). In this case, the system operates as in the open-loop case, since the actuator is at its maximum (or minimum) limit, regardless of the process output value. The control error decreases more slowly than in the ideal case (where there are no saturation limits), and therefore, the integral term becomes large (it *winds up*). Thus, even when the value of the process variable attains that of the reference signal, the controller still saturates due to the integral term, and this generally yields large overshoots and settling times.

In order to cope with this problem, an additional functionality designed for this purpose can be conveniently used. This can be done in different ways. For example, in the conditional integration approach, the integration is stopped when the control variable saturates and the control error and the control variable have the same sign. Alternatively, in the back-calculation approach, the integral term is recomputed when the controller saturates by feeding back the difference of the saturated and unsaturated control signal.

Tuning

The selection of the PID parameters, i.e., the tuning of the PID controller, is obviously the crucial issue in the overall controller design. This operation should be performed in accordance with the control specifications (which should take into account the set-point following, the load disturbance rejection, the control effort, and the robustness of the system). A major advantage of the PID controller is that its parameters have a clear physical meaning, and therefore, manual tuning is relatively simple. For example, for stable processes, increasing the proportional gain leads, in general, to a faster but more oscillatory response. In fact, by increasing K_p for the same value of the control error, the proportional control action increases, and so does the aggressiveness of the controller. Then, increasing the integral time constant (i.e., decreasing the effect of the integral action) results, in general, in a slower response but in a more damped system. This is because a larger value of T_i implies a smaller value of the control action at a given time instant of the transient response (assuming the same values of the past control errors). Finally, increasing the derivative time constant gives a damping effect. Indeed, if the set point is constant, the derivative action is proportional to the derivative of the process variable with a negative sign, and therefore, the

derivative action increases (with a negative sign) when the slope of the transient response increases (so that a big overshoot is avoided). However, in this context, much care should be taken to avoid increasing the derivative time constant too much as an opposite effect might occur in this case and an unstable system could eventually result. This is because the prediction over a too long time interval might be wrong.

The above considerations can be understood by considering a transient response in the time domain but also by considering the frequency response of the system and how it changes by modifying the PID parameters. For example, the effect of increasing the three controller actions can be seen as translating any point of the Nyquist plot in each of the directions shown in Fig. 1. From another point of view, analogous considerations can be done by considering the Bode plot. For example, considering a PID controller in ideal form with a filter on the overall control action, the effect of modifying the three parameters in the controller Bode plot is shown in Fig. 2. The effects of the parameter modification in the achieved performance can be better ascertained by plotting the frequency response of the loop transfer function for different cases. As an example, consider the process $P(s) = 1/(10s + 1)e^{-4s}$ and the PID controller $C(s) = K_p(1 + \frac{1}{T_i s} + T_d s)\frac{1}{T_f s + 1}$

PID Control, Fig. 1 Effect of an increment of the three PID control actions on a point of the Nyquist plot

PID Control, Fig. 2 Effect of an increment of three PID parameters on the controller Bode plot. The modifications are considered separately, namely, two parameters are fixed, while the other is modified

where the parameters are in the following ranges: $K_p \in [2, 15/4]$, $T_i \in [4, 16]$, $T_d \in [1.5, 4]$, being always $T_f = 0.1$. From Fig. 3, it appears that an increment of K_p yields an increment of the bandwidth and a decrement of the phase margin. Conversely, an increment of T_i has an opposite effect. Finally, it can be seen that the increment of T_d initially yields to an increment of the bandwidth and of the phase margin at the same time, but then a sudden increment of the bandwidth occurs, and this corresponds to a sudden decrement of the phase margin (because of the dead time of the process) with a possible loss of stability.

In any case, in order to ease the procedure, a large number of tuning rules have been proposed in the last century, starting from the well-known Ziegler–Nichols ones (Nichols and Ziegler 1942). Different approaches in this context are analyzed hereafter.

Empirical Tuning

Empirical tuning methods (like the Ziegler–Nichols and its refinements, Cohen–Coon, or Chien–Hrones–Reswick ones (O'Dwyer 2006)) consist in selecting the parameters of the PID controllers by using some empirical formulae which give the PID gains based on parameters of the process. Usually, the process parameters are those of a first-order-plus-dead-time (FOPDT) model or the ultimate gain and frequency of the process itself (the ultimate gain is the largest value of a proportional-only control that produces a sustained oscillation of the process variable, that is, that results in a marginally stable closed-loop system, while the ultimate frequency is the frequency of the corresponding sustained oscillation). These parameters can be obtained by means of a simple open-loop (step response) or closed-loop (relay feedback) experiment.

Model-Based Tuning

In model-based tuning (like the Dahlin's and Haalman's methods and the Internal Model Control one (O'Dwyer 2006)), the PID control law is determined analytically starting from a process model and by selecting an appropriate (closed-loop) target transfer function. The user

generally selects the desired closed-loop time constant as a tuning parameter which allows the handling of the trade-off between aggressiveness and robustness (and control effort). In this context, according to the well-known SIMC (Simplified Internal Model Control) tuning rules (Skogestad 2003), the closed-loop time constant should be selected equal to the dead time of the process.

Optimal Tuning

Optimal tuning rules aim at minimizing a given objective function. Usually, an integral function of the control error is selected for this purpose, for example,

$$J = \int_0^\infty t^n e^2(t) dt \quad (16)$$

where $n = 0, 1, 2$ or the Integrated Absolute Error

$$IAE = \int_0^\infty |e(t)| dt. \quad (17)$$

By solving the optimization problem for different kinds of (normalized) processes and by interpolating the results, it has been possible to obtain tuning formulae that give the PID gains based on the process parameters. Actually, it should be noted that as no (robustness) constraints are considered in the optimization procedure, a poor robustness may eventually result in the control system.

Robust Tuning

Recently, tuning rules which explicitly consider the robustness issue have been devised. In particular, the maximum of the sensitivity function is often considered as robustness index. A selected value of M_s is then employed as a constraint in finding the optimal PID parameters which minimize a given performance index. An additional constraint on the maximum complementary sensitivity function can also be considered. For example, the AMIGO tuning rules (Åström and Hägglund 2004) have been devised by applying this approach, where the integral gain is maximized in order to obtain the best reduction of load disturbances.

PID Control, Fig. 3

Example of the effect of an increment of three PID parameters on the loop transfer function Bode plot. The modifications are considered separately, namely, two parameters are fixed, while the other is modified

Automatic Tuning

The functionality of automatically identifying the process model and tuning the controller based on that model is called automatic tuning (or, simply, auto-tuning) (► [Autotuning](#)). In particular, an identification experiment is performed after an explicit request of the operator, and the values of the PID parameters are updated at the end of it (for this reason, the overall procedure is also called *one-shot automatic tuning* or *tuning-on-demand*). The design of an automatic tuning procedure involves many critical issues, such as the choice of the identification procedure (usually based on an open-loop step response or on a relay feedback experiment), of the a priori selected (parametric or non parametric) process model, and of the tuning rule.

The one-shot automatic tuning functionality is available in practically all the single-station controllers available on the market. More advanced control units might provide a *self-tuning* functionality, where the identification procedure is continuously performed during routine process operation in order to track possible changes of the system dynamics and the PID parameters values are adaptively modified. In this case, all the issues related to adaptive control have to be taken into account. In particular, performance assessment methodologies, which are capable to evaluate if the PID design can be improved, are of significant relevance in this context (► [Controller Performance Monitoring](#)).

Design Tools

Although one of the major advantages of PID controllers is their relative simplicity, Computer-Aided Control System Design tools (► [Computer-Aided Control Systems Design: Introduction and Historical Overview](#)) have been developed in order to help the user in their design (starting from the identification of the process) by taking into account the different control requirements in a given application (Guzman et al. 2008). In this context, all the additional functionalities can be considered, as well as more complex control

architectures where, in any case, the PID control is still the basic element (► [Control Structure Selection](#), ► [Control Hierarchy of Large Processing Plants: An Overview](#)).

Summary and Future Directions

PID controllers are the most employed controllers in industry, and the knowledge about their use is well established, with the presence of many effective tuning and automatic tuning techniques. Despite this, PID controllers are still being developed under many points of view. For example, design methodologies for more complex control schemes (like cascade control or control of multivariable systems with or without the use of a decoupling strategy) can be improved. Further, the advancement of the technologies poses new problems that need to be addressed. For example, the use of wireless sensors and actuators calls for event-based PID controllers whose design should take into account the asynchronous sampling. The availability of faster and faster microprocessors has also stimulated an increasing interest in fractional-order PID controllers which allows a more flexible design at the expense of an increment of the complexity.

PIDs and Biquads: Practical Control of Mechatronic Systems

Daniel Abramovitch
Mass Spec Division, Agilent Technologies,
Santa Clara, CA, USA

Abstract

The Proportional plus Integral plus Derivative (PID) controller is the most ubiquitous

feedback controller design, in industry, in consumer products, and even in first collegiate controls classes. While PID controllers are the preferred “Brand-X”/whipping boy of numerous doctoral theses on control, most of these comparisons go no further than simulation. In practice, it takes a lot of extra effort to justify replacing a PID controller. This entry discusses the main points of the PID + filter architecture (Abramovitch (2015c) Trying to keep it real: 25 years of trying to get the stuff I learned in grad school to work on mechatronic systems. In: Proceedings of the 2015 Multi-Conference on Systems and Control. IEEE, Sydney, pp 223–250) that is the mainstay of mechatronic control systems.

Keywords

PID control · Mechatronics · Filtering · Biquads · System ID

Introduction

Part of the popularity of PID controllers in practice is that many of the systems to which they are applied, whether they be temperature control, pressure control, or chemical process control (CPC), are reasonably modeled as first- or second-order systems. Complexity comes in the form of time delay, physical system changes, and/or nonlinearities. PID controllers are typically more than adequate for most systems modeled by a first- or second-order transfer function (Fig. 1).

Mechatronic systems are defined as systems with tight interactions between mechanical and electrical components. Such systems can have critical frequencies ranging from sub Hertz range up to hundreds of kiloHertz (or even megaHertz for nano-mechanical systems). Unlike the former systems, mechatronic systems often exhibit electrical or mechanical flexibilities that result in resonances and antiresonances when viewed in the frequency domain. While many of these systems have enough separation between the “rigid body” second-order system and the

PIDs and Biquads: Practical Control of Mechatronic Systems, Fig. 1 A practical digital control loop for a single-input, single output (SISO) mechatronic system. The digital controller is often implemented as a PID-

like controller in series with filtering to equalize the effect of high-frequency resonances and antiresonances (Abramovitch 2015c)

higher-frequency dynamics to be controlled using low-frequency PID controllers, they differ from non-mechatronic systems in that these dynamics (resonances and antiresonances) often show up in the desired control bandwidth and must be addressed.

PID Concepts

While PID controllers are the most standard controller used in practice, the PIDs themselves suffer from a lack of standardization. Virtually any control structure that has a proportional gain, an integrator with its own gain, and a differentiator with its own gain can be considered a PID controller, but the specification of gains can have a multitude of styles (Abramovitch 2015d). Consider the following three PID controller equations. The center term for each is the typical “three-parameter” form, while the rightmost term puts the PID in the form of an analog filter. For brevity, we have omitted the cases when a low-pass filter is added to the differentiator term (or on the entire PID), although this would be necessary if the PID were to be implemented in analog (continuous-time) form or discretized with a trapezoidal rule equivalent (Abramovitch 2015d). Still, these three forms are close to the style of specification of most continuous-time, unfiltered PID controllers that may be encountered, either in analysis or in commercial controllers. Recognizing one of these forms, we should be able to easily translate the control parameters into one of the other forms. This is extremely useful in getting an apples-to-apples

comparison of different commercial PID controllers.

$$\begin{aligned} C(s) &= K \left(1 + \frac{1}{T_I s} + T_D s \right) \\ &= K T_D \left(\frac{s^2 + \frac{1}{T_D} s + \frac{1}{T_I T_D}}{s} \right) \end{aligned} \quad (1)$$

$$\begin{aligned} C(s) &= K_P + \frac{K_I}{s} + K_D s \\ &= K_D \left(\frac{s^2 + \frac{K_P}{K_D} s + \frac{K_I}{K_D}}{s} \right) \end{aligned} \quad (2)$$

$$\begin{aligned} C(s) &= K_P + \frac{K_I}{T_I s} + K_D T_D s \\ &= K_D T_D \left(\frac{s^2 + \frac{K_P T_I}{K_D T_I T_D} s + \frac{K_I}{K_D T_I T_D}}{s} \right) \end{aligned} \quad (3)$$

The form of Eq. 1 is typically – but not always – associated with process control applications, temperature, and pressure control (Seborg et al. 2016). There is an overall controller gain, but the relative gains of the three parts are adjusted via the terms T_I and T_D , which nominally are meant to refer to the integration time (time over which the integral takes place) and differentiation time (time over which the derivative takes place), respectively. Even here, the terminology is confusing, since as written the integral and differentiator take place over all time. These terms take the place of the integrator and differentiator gains, although one might naturally assume that integration and differentiation times

would be characteristics of the device, rather than a tunable constant.

The form of Eq. 2 has three independent PID “knobs” with no hint of relation to the integration and differentiation time. The form of Eq. 3 breaks the integration and differentiation times out from the integrator and differentiator gains. While this

last form may seem a bit tedious due to the extra coefficients, it has a distinct advantage when discretized using a backward rectangular rule equivalent (Franklin et al. 1998) where $s \rightarrow \frac{z-1}{T_S z}$. If one sets $T_S = T_I = T_D$, which aligns with integration and differentiation over a single sample period, we get:

$$\begin{aligned} C_B(z) &= K_P + \frac{K_I}{1 - z^{-1}} + K_D(1 - z^{-1}) \\ &= (K_P + K_I + K_D) \left(\frac{1 - \frac{2K_D + K_P}{K_P + K_I + K_D} z^{-1} + \frac{K_D}{K_P + K_I + K_D} z^{-2}}{(1 - z^{-1})z^{-1}} \right) \end{aligned} \quad (4)$$

What is most revealing about this form is the similarity between the structures of Eqs. 3 and 4 as demonstrated in Fig. 2. The continuous and discrete parameters are related via $T_I = T_D = T_S$, while the structure remains essentially the same. Furthermore, the backward rectangular rule discretization has taken a non-proper analog PID form and made it a proper and therefore directly implementable discrete form.

While the denominator of Eq. 4 does not change with PID parameters, the numerator can produce anything from a lag filter (set $K_D = 0$) to a lead filter (set $K_I = 0$) to a notch filter (Abramovitch 2015d; Abramovitch et al. 2008). Figure 3 shows the ranges of a typical mechatronic control system. If the loop is closed well below the resonance, a PI controller may be used. If the loop is closed far above the resonance, a PD controller may be employed. (One might still use a small nonzero I gain to achieve zero steady-state error to a step.) It is when we try to close the loop in the vicinity of the resonance that we need to carefully use all the PID coefficients (Abramovitch et al. 2008), and so we need a far more accurate model than the previous two cases.

Another bridge between PID controllers and advanced methods is to realize that almost any linear SISO state space controller can be formulated as a PID plus a group of matched filters. Looking at it this way, the matched filters correspond to the estimator model, and neither of them works well if the modeling is inaccurate.

Generally, for systems beyond a double integrator, successful modeling involves a deep dive into measurements.

Filtering Higher-Order Dynamics

One of the distinguishing characteristics of mechatronic control systems is the commonality of flexibility in the physical system that manifests itself in the form of resonances and antiresonances. Generally, these dynamics do not lend themselves to identification via step response methods, relay methods, or most discrete-time, time domain methods (next section). Here we are more concerned with how to compensate for higher-frequency dynamics, and this involves filtering. The more accurate the filter model and (usually) the discrete implementation of that model, the more effectively we can control the system (Fig. 4).

Identifying a Plant Model

The key issue in being able to push the performance of any control design is a deep understanding and accurate model of the physical system. Traditionally, PID controllers were attached to slow process systems, and the gains were manually adjusted until the closed-loop system oscillated and then reduced back down. A well-known

PIDs and Biquads: Practical Control of Mechatronic Systems, Fig. 2 A parallel form topology of a simple analog PID controller (left). The digital PID controller

(right) shows much of the same structure. The similarity between these is not coincidental, but owes to how most PID designs are discretized

PIDs and Biquads: Practical Control of Mechatronic Systems, Fig. 3 The typical ranges in a mechatronic system and how they relate to PID control

procedure for this is Ziegler-Nichols, but other methods have supplanted it.

The first is to apply a step to the input of the physical system (left side of Fig. 5), observe the response, and extract dynamic parameters from these. In fact, step response methods are the main way of characterizing slow process systems that are not well suited for frequency response

methods. The issues with step response are that while they can be performed on any order system, one can only reasonably extract parameters from them if one assumes either a first- or second-order model ahead of time and then extracts the parameters associated with that model. The relay method replaces the controller in the loop by a signum function (the relay) to force an oscillation

PIDs and Biquads: Practical Control of Mechatronic Systems, Fig. 4 On the left: a high-order digital filter used in compensation implemented as a ratio of discrete polynomials. On the right: the same filter broken up into a

series of biquad filters which are more numerically stable and retain more of the original physical system dynamics structure

PIDs and Biquads: Practical Control of Mechatronic Systems, Fig. 5 On the left, zoomed in step response of stable second-order system with low damping and transport delay. On the right, a pair of frequency response func-

tions (FRFs) for the X axis of an AFM stage, computed via fast Fourier transform (FFT) and stepped-sine methods (Abramovitch 2015a). (Courtesy: Jeff Butterworth.)

of the closed-loop test system so as to back out the plant dynamics (Åström and Hägglund 2005). However, as with step response methods, it is only applicable when there are no significant resonances in the loop.

In this area, the most successful methods involve injecting signals across multiple frequencies and relating the output response to the input resulting in a frequency response function (FRF) (sometimes referred to in the academic literature as the empirical transfer function estimate). This

FRF may either be used in direct frequency domain design or to generate a parametric system model for control system design. The limits on these methods are often based on the sharpness of these extra dynamics (relating to their level of damping) and their proximity to one another. Different frequency domain methods have different levels of resolution, with the stepped-sine (known alternately as sine-dwell or in industry as swept-sine) method being the gold standard (Abramovitch 2015a). Frequency

PIDs and Biquads: Practical Control of Mechatronic Systems, Fig. 6 On the left: measured plant, compensator (PID + multinotch), and generated open-loop frequency response for AFM x-axis actuator. The PID and multinotch are automatically tuned to generate an open-loop response that looks like an integrator over the frequency range of interest, allowing the open-loop

crossover to be set subject to phase-margin constraints (Abramovitch 2015c). On the right: the measured closed-loop response. Note the nice, low-pass look of the closed-loop response and the minimal peaking. The closed-loop bandwidth can be adjusted from open-loop constraints or closed-loop peaking constraints

domain methods require that the input to the physical system have a rich spectral content and have a presumption that this will cause the output to also be spectrally rich. While methods based on the fast Fourier transform (FFT) are computationally faster than stepped-sine methods, the right side of Fig. 5 shows that when applicable, the stepped-sine produces much cleaner results. There are some drawbacks to any frequency domain method. The first is that the frequency response usually has to be converted to a parametric model in order to do design (Abramovitch et al. 2008). The second is that they are not really appropriate for heavily nonlinear systems or for systems with extremely slow time constants, such as those found in chemical process control or biological systems.

The critical point here is that the ability to push the performance of the control system design is directly tied to the confidence one has in the system model, and the latter depends very strongly on the types of measurements one can make on the system. Frequency response methods work very well in mechatronic systems, but they are less common in slow process applications where the time constants are on the orders of seconds or minutes.

Putting It All Together: An Example

Figure 6 shows an example that puts together the ideas of the previous sections. The system is identified using a stepped-sine method built into the controller (Abramovitch 2015a) resulting in the curve in the left plot. The clean response allows a controller to be generated (cyan curve) that equalizes the open-loop response (green curve) to look like an integrator up to the point at which the measurement gets too noisy. The controller is segmented into a PID to handle the lower-frequency behaviors and a series of biquads known as a multinotch (Abramovitch 2015b). The net result of this is that the open-loop crossover can be relatively close to the plant resonance and the closed-loop response (right plot) looks like a very clean low-pass filter with minimal peaking.

Summary

When something keeps working, over and over again across multiple situations, one can assume that that something is pretty effective. The class of PID controllers, despite being the whipping

boy of many a graduate student's doctoral thesis – is the most commonly used control law design because it can easily be applied to control second-order systems. Combining that with engineers' ability to beat many problems into second-order systems, we have a winning combination. For mechatronic systems, those percussions often involve adding filters to equalize out the open-loop dynamic response, allowing the PID to control the lower-frequency behavior of the physical system, while the filters (often implemented as string of biquads) compensate for the higher-frequency terms. The accuracy to which this can be done often depends on the knowledge of the physical system model, but even then a PID plus filters approach can often yield excellent results in practical systems.

Pilot-Vehicle System Modeling

Aleksandr Efremov

Moscow Aviation Institute, Moscow, Russia

Abstract

The main types and variables of pilot-aircraft systems and pilot control response characteristics are considered. The basic regularities of pilot behavior exposed in closed-loop systems are briefly discussed. Different types of models of pilot behavior are reviewed including classical (McRuer), structural, and optimal control models.

Keywords

Pilot behavior · Manual control · Describing function · Remnant spectral density · Crossover pilot model · Structural model · Pilot optimal control model

Introduction

The effective use of piloted flight vehicles has always required a satisfactory match of vehicle characteristics (which include vehicle dynamics, flight control system, inceptors, displays) with the human pilot's characteristics as a flight controller. The provision of proper vehicle handling qualities by the flight control system and display and manipulator design has often posed serious

problems which the vehicle system engineer must solve.

The solutions of the problems require the knowledge of mutual interactions between the pilot and the vehicle. The understanding of such interactions requires a mathematical theory which can be used to explain known findings and to predict new ones. For handling qualities, such a theory should be based on the methods of control engineering and treat the pilot-vehicle system as a closed-loop (in general, a multiloop) entity. The sine qua non of the theory is a model of pilot dynamic characteristics in a form suitable for application using relatively conventional control engineering techniques. An adequate description of a pilot's dynamics response characteristics is not easily obtained because of the pilot's inherent adaptability and capacity for learning.

Main Variables of the Pilot-Aircraft System

The pilot-aircraft manual control system, shown in Fig. 1, is characterized by a number of variables. The main group of these variables is the so-called task variables, which comprise all the system inputs (command inputs i , disturbances d) and control system elements (display, manipulators, and controlled element dynamics, which is defined by the aircraft frame and flight control system dynamics).

A specific feature of pilot-aircraft systems is the dependence of the piloting task on the task variables. For different piloting tasks, these variables or their parameters differ too. Stability of the closed-loop system is always a necessary, though not sufficient, criterion for the control strategy. Consequently, the pilot's dynamics are profoundly affected by the display and controlled element dynamics, because pilot response must be adapted to provide the necessary loop stability and accuracy. The characteristics of the other task variables (i , d), related to the mission and control strategy, also exert direct influence on the pilot dynamics, although their effects are more in the nature of adjustment and emphasis than of changes in fundamental regularities of pilot behavior.

These variables constitute an enormous range of possible conditions and piloting tasks. In addition to the task variables, the other groups of variables – procedural (p – instructions, training schedule order of presentation of trials, etc.), environmental (ε – illumination, vibration, temperature, and so forth), pilot centered (σ – physical condition, motivation, etc.) – have less influence on pilot-aircraft system features.

Types of Pilot-Aircraft Systems

The structure of the pilot-aircraft system depends on the piloting task. Some tasks (e.g., the pitch tracking task) can be interpreted with the help of the single loop compensatory block diagram (Fig. 1). In that case the pilot perceives only the error signal, $y(t) = e(t) = i(t) - x(t)$. The pitch angle tracking task can be interpreted in this way. The other tasks require more complicated descriptions. For example, the landing task is a multiloop compensatory task, where the inner loop closed by the pilot is the pitch control loop. Some piloting tasks are multichannel control tasks, in which the pilot perceives several visual stimuli (e.g., pitch angle and bank angle) and generates commands in several channels too. Pilots also perceive stimuli of different sensing modalities (visual, vestibular, proprioceptive). In cases where these influence the pilot's actions, the multimodality of the pilot-aircraft system has to be analyzed.

Many past experiments, in which human dynamic measurements were taken, have been conducted for investigation of compensatory tracking tasks. Some practical piloting tasks (e.g., aim-to-aim tracking in case when the target flies against a background of clouds) correspond to pursuit conditions. In that case, the pilot perceives the error signal $e(t)$ and the input signal $i(t)$. When flying through a mountain gorge or while driving a car, the operator sees the future trajectory $i(t + t^*)$ with preview over a certain time interval t^* . Previous studies of pilot operator behavior in preview tracking tasks demonstrated the considerable difference of the pilot and the pilot-aircraft system characteristics in comparison with the characteristics measured

Pilot-Vehicle System Modeling, Fig. 1 Pilot-aircraft system

Pilot-Vehicle System Modeling, Fig. 2 Quasi-linear paradigm for the human pilot

in compensatory tracking tasks. In particular, the tracking performance (variance of error) is lower 2.5 to 3.5 times when $t^* = 0.5 \div 1$ s.

In many piloting tasks the single loop compensation system defines the main features of more complicated types of pilot-aircraft systems and its flying qualities. Therefore, this type of the system has been investigated in more depth.

Pilot Control Response Characteristics

The most obvious aspect of human dynamic behavior in a manual control task is the pilot's control actions within that task. When the key variables are fixed and the signals in the control loop are approximately time invariant over an interval of interest, the pilot-vehicle system can be presented as a quasi-linear system. In that case, the pilot response can be presented by

two components: the pilot-describing function, $W_p(j\omega)$, taking into account the linear portion of pilot response on the stimulus $e(t)$, and remnant $n_e(t)$, which takes into account all nonlinear, nonstationary effects of pilot behavior (Fig. 2).

In the majority of piloting tasks, $n_e(t)$ is a stationary process characterizing the remnant spectral density $S_{n_en_e}(\omega)$ (McRuer and Krendel 1974). The pilot control response characteristics $W_p(j\omega)$ and $S_{n_en_e}(\omega)$ depend explicitly on the task variables (McRuer and Jex 1967; McRuer et al. 1968). In much experimental research, the technique for identification of these characteristics was based on the use of an input signal consisting of the sum of non-harmonically related sine waves with cut-off frequency ω_i at 1.5, 2.5, and 4 rad/s and different controlled element dynamics (Allen and Jex 1972; Magdaleno 1972; Shirley 1969).

In addition to control response, other types of responses also characterize pilot's behavior: physiological (F) and psychophysiological ψ responses (Fig. 1). For one of the psychophysiological response characteristics, the pilot opinion rating (PR) is widely used in experimental investigations as well as for the measurement of pilot control response. Pilot opinion ratings are defined by specialized scales (e.g., the Cooper-Harper scale Cooper and Harper 1969).

Modeling Pilot Behavior in Manual Control

Experimental investigations have demonstrated a specific regularity: for a variety of forcing functions and controlled elements the slope of the open-loop describing function $|W_{OL}(j\omega)|$ vs frequency was *unity*, that is, -20 dB/dec in the region of the crossover frequency ω_c (McRuer and Jex 1967). This observation has led to the conclusion that near ω_c , $W_{OL}(j\omega)$ can be presented by the “crossover model” (McRuer and Jex 1967)

$$W_{OL}(j\omega) = W_p(j\omega) \cdot W_C = \frac{\omega_c}{j\omega} e^{-j\omega\tau_e}$$

This model has two parameters:

$$\omega_c = \omega_{co}(\omega_c) + \Delta\omega(\omega_i)$$

$$\tau_e = \tau_o(\omega_c) + \Delta\tau(\omega_i)$$

For the controlled element dynamics $W_C = \frac{K}{s(Ts+1)}$, the increase of constant T leads to an increase of τ_0 and a decrease of ω_{C0} . The empirical dependences $\Delta\omega_c$ and $\Delta\tau_e$ on ω_i obtained for the rectangular form of input spectrum are the following: $\Delta\omega_c = 0.18\omega_i$, $\Delta\tau = -0.07\omega_i$.

McRuer proposed several modifications of the open-loop system crossover and pilot describing function models with different levels of accuracy of human neuromuscular system description (McRuer and Krendel 1974). One of the simplest ones (used widely by many researchers), which might be recommended for

description of pilot-aircraft system characteristics in the crossover frequency range, is the following

$$W_p(j\omega) = K_p \frac{T_L j\omega + 1}{T_1 j\omega + 1} e^{-j\omega\tau_e}$$

The selection of the parameters K_p , T_L , and T_1 is carried out by using “adjustment rules” so that the closed-loop system conforms to experimental frequency response characteristics. These adjustment rules reflect the main features of pilot behavior – adaptation and optimization.

A more complicated model of pilot describing function (“structural model”) was offered by R. Hess (1979, 1984). It takes into account the additional inner loop generated by the pilot as a result of his response to proprioceptive cues. The modification of this model (Efremov and Tjaglik 2011) (Fig. 3) demonstrated good agreement with the pilot describing function as measured in experiments. One of the features of this modified model is the criterion used for the parameter optimization: $I = \min[\sigma_e^2]$ or $I = \min[\sigma_e^2 + \beta\sigma_n^2]$. This procedure requires the knowledge of the pilot remnant spectral density. For the single loop system, such a model was developed by Levison et al. (1969).

$$S_{n_e n_e}(\omega) = 0.01\pi \frac{\sigma_e^2 + \sigma_e^2 T_L^2}{1 + T_L^2 \omega^2}$$

In a limited number of researches, the classic approach to pilot modeling considered above was used for more complicated types of the pilot-aircraft system, when the pilot perception of motion cues was taken into account (multimodality system Hess 1990) or for a case of the multi-loop pilot-aircraft system (Stapleford et al. 1967).

A different approach to pilot behavior modeling was developed by Kleiman et al. (1970). It is based on the modern optimal control theory and assumes that the pilot's goal is to minimize the cost function:

$$I = \lim_T \frac{1}{T} \int_0^T (x Q x^T + u Q_c u^T + \dot{u} G_c \dot{u}^T) dt$$

The model takes into account the main pilot limitation parameters: time delay in perception,

Pilot-Vehicle System Modeling, Fig. 3 Pilot structural model

Pilot-Vehicle System Modeling, Fig. 4 Optimal pilot model

the observation and motor noises, and the neuromuscular dynamics.

The predictive part of the model consists of the optimal controller ($-L^*$), Kalman filter, and predictor (Fig. 4). The software for definition of these elements allows the use of this model for the different types of structural the pilot-aircraft systems.

The classical, structural, and optimal pilot behavior models have been applied widely for different manual control tasks: the development of alternative criteria for flying qualities (Neal and Smith 1971; Efremov et al. 1998), the flight control system (Schmidt 1979) and display design (Klein and Clement 1973; Efremov and Tjaglik 2011; Mulder 1999; Grunwald 1985), exposition of the reasons of preview, and the analysis of reasons for pilot-induced oscillation (McRuer 1997) and the development of means for its suppression (Efremov 1995). A more precise pilot structural model taking into account the model of neuromuscular system and proprioceptive loop was used for the exposition of the reasons of biodynamic interaction effects, the influence of the type of inceptors and feel system dynamics on the pilot-aircraft system characteristics (Zaichik 2014).

In some of the researches, attempts have been made to find the relationship between the parameters of the closed-loop system, pilot control response characteristics, and pilot opinion ratings. The technique developed in these researches is called the “paper pilot technique” (Anderson 1970). The following modification of this technique has enabled a close match between the results of mathematical modeling (PR, T_L , variance of error, etc.) of the different types of the pilot-aircraft system and the results of experimental investigations (Efremov and Ogloblin 2006).

Summary and Future Directions

Pilot behavior has been studied extensively for single-loop stationary manual control tasks. Two approaches to the mathematical modeling of the pilot behavior have been developed: classical and optimal control. Both of them have produced good agreement with experimental results. The discussed models describe one of the main features of the pilot adaptation – “parameter adaptation,” when a change of any task variable causes a change of human operator control response characteristics. Only a limited number

of experimental investigations have been carried out for more complicated cases: multiloop and multimodality pilot-aircraft closed-loop systems. Broader investigations are necessary in the future to obtain accurate pilot mathematical models for these cases. Future investigation of pilot behavior modeling is also necessary for better formulations of other aspects of pilot adaptation:

- “Structural adaptation,” that is, when the pilot selects the loops and the best type of behavior (compensatory, pursuit, preview, etc.) appropriate for the different task variables and, in the case of the flight control system, changes in dynamics.
- “Goal adaptation,” that is, when a change of the piloting task or a failure in the controlled element dynamics is accompanied by a change of the goals.

Other future directions in pilot modeling are the development of models to predict the results in the case of sharp changes of controlled element dynamics, the optimization of the controlled element dynamics, the definition of the relationship between the pilot’s control response characteristics and his/her opinion rating in different piloting tasks, getting new criteria for the handling qualities, prediction of pilot-induced oscillations, and solving many other manual control problems.

Polynomial/Algebraic Design Methods

Technical University of Prague, Prague, Czech
Republic

Abstract

Polynomial techniques have made important contributions to systems and control theory. Algebraic formalism offers several useful tools for control system design. In most cases, control systems are designed to be stable and to meet additional performance specifications, such as optimality or robustness. The basic tool is a parameterization of all controllers that stabilize a given plant. Optimal or robust controllers are then obtained by an appropriate selection of the parameter. An alternative tool is a reduction of controller synthesis to a solution of a polynomial equation of specific type. These two polynomial/algebraic approaches will be presented as closely related rather than isolated alternatives.

Keywords

Controller synthesis · Linear systems · Polynomial equation approach to control system design · Youla-Kučera parameterization of stabilizing controllers

Stabilizing Controllers

The majority of control problems can be formulated using the diagram shown in Fig. 1. Given a plant S , determine a controller R such that the feedback control system is stable and satisfies some additional performance specifications, such as reference tracking, disturbance attenuation, optimality, or robustness.

Suppose that the plant and the controller are linear time-invariant single-input single-output continuous-time systems with real *rational* transfer functions S and R , respectively. Stability is understood as the *input-output stability*, i.e., whenever the exogenous inputs δ and ρ are essentially bounded in amplitude, so too are the output signals μ and η (hence also ε and ν).

It is natural to separate the design task into two consecutive steps: (1) stabilization and (2) achievement of additional performance specifications. To do this, all solutions of the first step, i.e., *all controllers that stabilize the given plant*, must be found.

How can one characterize such controllers? Denote H_s the reference-to-error transfer function (sometimes called the sensitivity function) and H_c the disturbance-to-control transfer function (the so-called complementary sensitivity function) in the closed-loop control system, namely,

$$H_s = \frac{1}{1 + SR}, \quad H_c = \frac{SR}{1 + SR}.$$

Now suppose that S can be expressed as the ratio of two coprime polynomials, $S = b/a$, and that the controller has alike form, $R = q/p$. Then the two closed-loop transfer functions can be written as

Polynomial/Algebraic Design Methods, Fig. 1
Feedback control system

$$H_s = a \frac{p}{ap + bq} := aX,$$

$$H_c = b \frac{q}{ap + bq} := bY$$

Consequently, if R stabilizes S , then the rational functions X and Y are bound to be stable. These functions cannot be arbitrary, however, since $H_s + H_c = 1$. The stability equation follows as

$$aX + bY = 1.$$

Any stabilizing controller for S can be expressed as $R = Y/X (= q/p)$, where X and Y are a stable rational solution pair of the stability equation. This solution can be expressed in parametric form:

$$X = x + bW, \quad Y = y - aW,$$

furnishing in turn an explicit parameterization of the set of all stabilizing controllers for S :

$$R = \frac{y - aW}{x + bW},$$

known as the *Youla-Kučera parameterization*. Here x and y are any polynomials satisfying the Bézout equation $ax + by = 1$, while W is a free parameter ranging over the set of stable real rational functions such that $x + bW$ is not identically zero.

Example 1 Consider an integrator plant $S(s) = 1/s$. The Bézout equation admits a solution $x = 0$, $y = 1$ so that the set of all stabilizing controllers for S is given by

$$R(s) = \frac{1 - sW}{W}$$

for any stable real rational $W \neq 0$.

The parameter

$$W(s) = \frac{1}{s + 1}$$

yields $R = 1$, a proportional gain controller. The parameter

$$W(s) = \frac{s}{s^2 + s + 1}$$

results in a proportional-integral controller

$$R(s) = 1 + \frac{1}{s}.$$

Taking $W = 1$ leads to the stabilizing controller $R(s) = 1 - s$. The feedback system is stable, but it has a pole at $s = \infty$.

Additional Performance Specifications

There is a simple formula that generates all the stabilizing controllers for a given plant. Using this formula, we can obtain a parameterization of all stable closed-loop transfer functions that can be obtained by stabilizing a given plant. The bonus is that the parameterization is *affine* in the free parameter W . In contrast, the controller R appears in a nonlinear fashion:

$$\begin{aligned} \begin{bmatrix} v \\ y \end{bmatrix} &= \frac{1}{1 + SR} \begin{bmatrix} 1 & R \\ S & SR \end{bmatrix} \begin{bmatrix} d \\ r \end{bmatrix} \\ &= \begin{bmatrix} a(x + bW) & a(y - aW) \\ b(x + bW) & b(y - aW) \end{bmatrix} \begin{bmatrix} d \\ r \end{bmatrix}. \end{aligned}$$

As R and W are in a one-to-one correspondence, it is convenient to use W in lieu of R in the design process and calculate R subsequently. Thus, the parameterization of all stabilizing controllers makes it possible to separate the design process into two steps: the determination of all stabilizing controllers and the selection of the parameter that achieves the remaining design specifications. The extra benefit is that both tasks are linear.

Asymptotic Properties

Asymptotic properties of control systems can easily be accommodated in the sequential design procedure. These include the elimination of an offset due to step references, the ability of system output to follow a class of reference signals, or the asymptotic elimination of specific disturbances.

In Fig. 1, asymptotic *reference tracking* means that the output η follows the reference ρ as time approaches infinity, which is to say that the error ε approaches zero for large times. On the other hand, we speak of asymptotic *disturbance elimination* if the effect of the disturbance δ decreases at the output η for increasing time. In terms of Laplace transforms, $\varepsilon = H_s \rho$ and $\eta = SH_s \delta$ are to be *stable* rational functions.

Example 1 Consider the plant $S(s) = 1/(s+1)$. The Bézout equation admits a solution $x = 0$, $y = 1$. The set of all stabilizing controllers for S is

$$R(s) = \frac{1 - (s+1)W}{W}$$

for any stable real rational $W \neq 0$. The achievable sensitivity transfer functions are $H_s = (s+1)W$.

To track a step reference, $\rho = 1/s$, we must take $W = sW_1$ for any stable rational $W_1 \neq 0$. To eliminate a sinusoidal disturbance, $\delta = s/(s^2 + \omega^2)$, we constrain the parameter as $W = (s^2 + \omega^2)W_2$ for any stable rational $W_2 \neq 0$. To meet both requirements, we simply take $W = s(s^2 + \omega^2)W_3$ for any stable rational $W_3 \neq 0$, say $W = s(s^2 + \omega^2)/(s+1)^4$.

The resulting controller is

$$R(s) = \frac{3s^3 + (6 - \omega^2)s^2 + (4 - \omega^2)s + 1}{s(s^2 + \omega^2)}.$$

The controller obtained in Example 1 demonstrates the internal model principle: the unstable modes to be followed or eliminated must be generated by the controller unless they are present in the plant.

H₂ Optimal Control

The sequential design procedure will be further illustrated on the design of *linear-quadratic*

optimal controllers. Given a plant with transfer function $S = b/a$, the task is to find a controller that stabilizes the control system of Fig. 1 while minimizing the H_2 norm of some closed-loop transfer function, say of the complementary sensitivity function H_c .

The H_2 norm is defined for any strictly proper rational function G analytic on the imaginary axis as

$$\|G\|_2 = \sqrt{\frac{1}{2\pi} \int_{-\infty}^{\infty} |G(j\omega)|^2 d\omega}.$$

The set of complementary sensitivity functions that can be achieved in the stabilized control system is

$$H_c = b(y - aW),$$

where W is a free stable rational parameter. The parameter will be selected so as to minimize the H_2 norm of H_c .

Let $\alpha\beta$ be a polynomial defined by keeping the stable (in $\operatorname{Re} s < 0$) zeros of ab while replacing the unstable (in $\operatorname{Re} s \geq 0$) ones with their negative values. Then $ab/\alpha\beta$ is inner (or all pass) and

$$\|H_c\|_2 = \left\| \frac{\alpha\beta}{ab} H_c \right\|_2 = \left\| \frac{\alpha y \beta}{a} - \alpha W \beta \right\|_2.$$

Consider the decomposition

$$\frac{\alpha y \beta}{a} = r + \frac{q}{a}$$

where r is a polynomial and q/a is strictly proper. With this decomposition,

$$\|H_c\|_2^2 = \left\| \frac{q}{a} \right\|_2^2 + \|r - \alpha W \beta\|_2^2$$

because q/a and $r - \alpha W \beta$ are orthogonal and thus the cross-terms contribute nothing to the norm. The last expression is a complete square whose first part is independent of W . Hence the minimizing parameter is $W = r/\alpha\beta$, and if it is indeed stable and admissible, it defines the unique optimal controller. Otherwise, no optimal controller exists.

The consequent minimum norm equals

$$\min_W \|H_c\|_2 = \left\| \frac{q}{a} \right\|_2.$$

Example 2 To illustrate, consider the plant $S(s) = 1/(s - 1)$. The class of all stabilizing controllers for S is found to be

$$R(s) = \frac{1 - (s - 1)W}{W}$$

for a free stable rational parameter $W \neq 0$. The complementary sensitivity transfer function is

$$H_c(s) = 1 - (s - 1)W.$$

Now $\alpha = s + 1$, $\beta = 1$ and the polynomial part of

$$\frac{\alpha\beta}{a} = \frac{s + 1}{s - 1} = 1 + \frac{2}{s - 1}$$

is $r = 1$. Thus H_c attains minimum H_2 norm for

$$W(s) = \frac{1}{s + 1}$$

and the corresponding optimal controller is $R(s) = 2$.

The optimal complementary sensitivity function is

$$H_c(s) = \frac{2}{s + 1}$$

and $\|H_c\|_2 = \sqrt{2}$.

Robust Stabilization

The notion of robust stability addresses stabilization of plants subject to modeling errors, when the actual plant may differ from the nominal model, using a fixed controller. The ultimate goal is to stabilize the actual plant. The actual plant is unknown, however, so the best one can do is to stabilize a large enough set of plants.

Thus the basis technique to model plant uncertainty is to model the plant as belonging to a set. Such a set can be either structured – for example, there is a finite number of uncertain parameters – or unstructured: the frequency response lies in a set in the complex plane for every frequency. The unstructured uncertainty model

is more important for several reasons. On the one hand, it is well suited to represent high-frequency modeling errors, which are generically present and caused by such effects as infinite-dimensional electromechanical resonance, transport delays, and diffusion processes. On the other hand, the unstructured model of uncertainty leads to a simple and useful design theory.

The unstructured set of plants is usually constructed as a neighborhood of the nominal plant, with the uncertainty represented by additive or multiplicative perturbations. The size of the neighborhood is measured by a suitable norm, most common being the H_∞ norm that is defined for any rational function G analytic on the imaginary axis as

$$\|G\|_\infty = \sup_\omega |G(j\omega)|.$$

Let us illustrate the design for *robust stability under unstructured norm-bounded multiplicative perturbations*. Consider a nominal plant with transfer function S and its neighborhood S_Δ defined by

$$S_\Delta := (1 + F\Delta)S$$

where F is a fixed stable rational function and Δ is a variable stable rational function such that $\|\Delta\|_\infty \leq 1$.

The idea behind this uncertainty model is that $F\Delta$ is the normalized plant perturbation away from 1:

$$\frac{S_\Delta}{S} - 1 = F\Delta.$$

Hence if $\|\Delta\|_\infty \leq 1$, then for all frequencies ω

$$\left| \frac{S_\Delta(j\omega)}{S(j\omega)} - 1 \right| = |F(j\omega)|$$

so that $|F(j\omega)|$ provides the uncertainty profile while Δ accounts for phase uncertainty.

Now suppose that R is a controller that stabilizes the nominal plant S . Applying the small gain theorem, R is seen to stabilize the entire family of plants S_Δ if and only if

$$\|H_c F\|_\infty < 1.$$

Polynomial/Algebraic Design Methods,

Fig. 2 Bode plots of F (dotted) and $e^{-0.2s} - 1$ (solid)

This is a necessary and sufficient condition for robust stabilization of the nominal plant S .

The set of all stabilizing controllers for $S = b/a$ is described by the formula

$$R = \frac{y - aW}{x + bW}$$

where $ax + by = 1$ and W is a free stable rational parameter. The robust stability condition then reads

$$\|b(y - aW)F\|_{\infty} < 1.$$

Any stable rational W that satisfies this inequality then defines a robustly stabilizing controller R for S . In case W actually minimizes the norm, one obtains the best robustly stabilizing controller.

Example 3 Consider a plant with the transfer function

$$S_{\tau}(s) = \frac{s+1}{s-1} e^{-\tau s}$$

where the time delay τ is known only to the extent that it lies in the interval $0 \leq \tau \leq 0.2$. The task is to find a controller that stabilizes the uncertain plant S_{τ} . The time-delay factor $e^{-\tau s}$ can be treated as a multiplicative perturbation of the nominal plant

$$S(s) = \frac{s+1}{s-1}$$

by embedding S_{τ} in the family

$$S_{\Delta} := (1 + F\Delta)S$$

where Δ ranges over the set of stable rational functions such that $\|\Delta\|_{\infty} \leq 1$. To do this, F should be chosen so that the normalized perturbation satisfies

$$\left| \frac{S_{\Delta}(j\omega)}{S(j\omega)} - 1 \right| = \left| e^{-j\omega\tau} - 1 \right| \leq |F(j\omega)|$$

for all ω and τ . A little time with the Bode magnitude plot shows that a suitable uncertainty profile is

$$F(s) = \frac{3s+1}{s+9}.$$

Figure 2 is the Bode magnitude plot of this F and $e^{-\tau s} - 1$ for $\tau = 0.2$, the worst value.

The task of stabilizing the uncertain plant S_{τ} is thus replaced by that of stabilizing every element in the set S_{Δ} , that is to say, by robustly stabilizing the nominal plant S with respect to the multiplicative perturbations defined by F .

The set of all stabilizing controllers for S is found to be

$$R(s) = \frac{0.5 - (s-1)W}{-0.5 + (s+1)W}$$

where $W \neq 0.5/(s+1)$ is any stable rational parameter. The robust stability condition reads

$$\|P - QW\|_{\infty} < 1$$

where

$$P(s) = 0.5(s+1) \frac{3s+1}{s+9},$$

$$Q(s) = (s-1)(s+1) \frac{3s+1}{s+9}.$$

Since Q has one unstable zero at $s = 1$, it follows from the maximum modulus theorem that the minimum of the H_{∞} norm taken over all stable rational functions W is $P(1) = 0.4 < 1$ and this minimum is achieved for

$$W(s) = \frac{P(s) - P(1)}{Q(s)} = \frac{1}{10} \frac{15s+31}{(s+1)(3s+1)}.$$

Thus, the robust stability condition is satisfied, and the corresponding best robustly stabilizing controller is

$$R(s) = \frac{2}{13} \frac{s+9}{s+1}.$$

Polynomial Equation Approach

In order to determine the set of all stabilizing controllers for a given plant, it is enough to determine one particular solution of the Bézout equation. It is therefore plausible that performance specifications in addition to stability can be met by selecting an appropriate solution of a polynomial equation that is related to the Bézout equation.

The reduction of controller synthesis to solving polynomial equations is referred to as the *polynomial equation approach* to control system design. The equations involved are Diophantine equations of the form

$$ap + bq = d$$

where a , b , and d are given polynomials and p , q are polynomials to be found. Such an equation is solvable for any d if and only if a and b are coprime polynomials. Then, the solution set is given by

$$p = p_0 + bt, \quad q = q_0 - at$$

where p_0 , q_0 is a particular solution and t is an arbitrary polynomial.

Such an equation is in fact the pole placement equation. Thus, pole placement is a prototype control problem.

Pole Placement

The requirement of stability places all closed-loop system poles within the left half-plane $\text{Re } s < 0$. Very often, however, we wish to allocate the poles to a specific region of the half-plane or to achieve specific pole positions.

Given a plant $S = b/a$, the set of all stabilizing controllers for S is

$$R = \frac{y - aW}{x + bW}$$

where x , y are polynomials such that $ax + by = 1$ and W is a free stable rational parameter. Let $W = w/d$ for a stable polynomial d . Then

$$R = \frac{dy - aw}{dx + bw} := \frac{q}{p}$$

and the closed-loop pole polynomial is given by

$$ap + bq = d(ax + by) = d.$$

Thus W parameterizes all stabilizing controllers for S , the denominator polynomial d of W specifies the positions of the control system poles, and the numerator polynomial w of W represents the remaining degrees of freedom, i.e., parameterizes all stabilizing controllers that assign the specified poles.

Example 4 Consider the plant $S(s) = 1/(s-1)$ and the set of stabilizing controllers for S :

$$R(s) = \frac{1 - (s-1)W}{W}, \quad W \neq 0.$$

Let the desired pole locations be given by the polynomial $d = s^2 + 2s + 1$. This is achieved by putting $W = w/d$ for an arbitrary numerator polynomial $w \neq 0$.

It is to be noted that d specifies the poles at *finite* positions only. Poles at $s = \infty$ will occur whenever R is not proper rational. To avoid this situation, w should be constrained to $w = s + \omega$ for any real ω . Then the set of controllers that achieve the desired pole placement is

$$R(s) = \frac{(3 - \omega)s + (1 + \omega)}{s + \omega}.$$

Alternatively, one can solve the pole placement equation $ap + bq = d$ directly. The solution set is

$$p = t, \quad q = s^2 + 2s + 1 - (s-1)t$$

and q/p is proper if and only if $t = s + \omega$, ω real.

H₂ Optimal Control

The H_2 optimal control is a special case of pole placement. Indeed, the optimal controller is given by

$$R = \frac{y - aW}{x + bW} = \frac{y - a\frac{r}{\alpha\beta}}{x + b\frac{r}{\alpha\beta}} = \frac{\alpha y\beta - ar}{\alpha x\beta + br} := \frac{q}{p}$$

and

$$\begin{aligned} ap + bq &= a(\alpha x\beta + br) + b(\alpha y\beta - ar) \\ &= \alpha\beta(ax + by) = \alpha\beta. \end{aligned}$$

Thus, the (finite) pole positions of the H_2 optimal control system are given by the pole polynomial $d = \alpha\beta$. The system has no poles at $s = \infty$ as the optimal complementary sensitivity function H_c is strictly proper.

The pole placement equation, however, has more than one solution. Which one is optimal? The one with q/a is strictly proper. It is the solution pair p, q with q having a least degree.

Example 5 Let us reconsider Example 2. As an alternative, one can solve the Diophantine equation

$$(s-1)p + q = s + 1$$

for the solution pair p, q such that $q/(s-1)$ is strictly proper. This yields the least-degree solution pair with respect to q , namely, $p = 1$, $q = 2$. The optimal controller is $R = q/p = 2$.

Summary and Future Directions

The benefits of representing stabilizing controllers by a single parameter include (1) easy accommodation of additional design specifications by selecting an appropriate parameter, (2) all transfer functions in a stabilized system are linear in the parameter (while they are nonlinear in the controller), and (3) the parameter belongs to a smaller set of stable rational functions (while the controller is any rational).

The results presented here for linear time-invariant systems with rational transfer functions can be generalized to extend the scope of the theory to include distributed-parameter systems, time-varying systems, and even nonlinear systems.

The transfer functions of distributed-parameter systems are no longer rational, and coprime factorizations cannot be assumed a priori to exist. The coefficients of time-varying systems are functions of time, and the operations of multiplication and differentiation do not commute. In nonlinear systems, transfer functions are replaced by input-output maps. Technical assumptions may prevent one from parameterizing the *entire* set of internally stabilizing controllers; still, the subset may be large enough for practical purposes. For many systems of physical and engineering interest, the above difficulties can be circumvented and the algebraic/polynomial approach carries over with suitable modifications.

Recommended Reading

The use of polynomials, in one way or another, in feedback control system design can be traced back to Newton et al. (1957) and Jury (1958). The authors noted that for a closed-loop system to be stable, H_c must absorb the plant unstable zeros. The plant was assumed to be stable; if this assumption were dropped, H_s would have been found to absorb the plant unstable poles. These conditions are equivalent to polynomial divisibility conditions and hence to the Bézout stability equation, which appears later in Kučera (1974).

The first attempt to use polynomials in an explicit manner is due to Volgin (1962), a student of Tsytkin. He obtained a solution of the pole placement problem through the solution of a polynomial equation, known as the pole placement equation. Åström (1970) published a polynomial equation solution to the minimum variance control problem for minimum-phase plants. The ultimate publication that presents the polynomial equation approach to multi-input multi-output control system design is Kučera (1979).

The underlying problem in any control system design is that of stability. It is logical to design the control system step by step: stabilization first and then the additional performance specifications. To do this, we need to know any and all stabilizing controllers for the given plant.

This problem was first addressed and solved for finite-dimensional, linear time-invariant systems using transfer function methods; see Larin et al. (1971), Kučera (1975), Youla et al. (1976a, b), and Kučera (1979). A state-space representation of all stabilizing controllers was derived later by Nett et al. (1984).

It took decades to appreciate the importance of the result and come up with applications. The

milestones were the observations by Desoer et al. (1980) that the polynomial fraction approach can be extended to linear systems with nonrational transfer functions, as well as the result by Hammer (1985) showing that the approach is applicable to a broad class of nonlinear systems. Further generalizations were obtained by Paice and Moore (1990), Anderson (1998), and Quadrat (2003, 2006).

The parameterization of all controllers that stabilize a given plant was labeled the Youla-Kučera parameterization in Anderson (1998). This result launched an entirely new area of research and has ultimately become a new paradigm for control system design.

Tutorial textbooks on this subject include Vidyasagar (1985), Doyle et al. (1992), and Kučera (2003, 2011). The reader is further referred to the survey papers by Kučera (1993), Anderson (1998), and Kučera (2007).

Advanced and recent applications of the Youla-Kučera parameterization include stabilization under constrained inputs (Henrion et al. 2001), robust stabilization with fixed-order controllers (Henrion et al. 2003), accommodation of time-domain constraints on inputs and outputs (Henrion et al. 2005a), and determination of least-order stabilizing controllers (Henrion et al. 2005b).

Port-Hamiltonian Systems: From Modeling to Control

Arjan van der Schaft

Bernoulli Institute for Mathematics, Computer Science and Artificial Intelligence, Jan C. Willems Center for Systems and Control, University of Groningen, Groningen, The Netherlands

Abstract

Port-based modeling of general multi-physics systems leads to port-Hamiltonian system formulations, which make explicit the underlying network and energetic structure. Key properties are (shifted) passivity, compositionality, and existence of conserved quantities. This provides powerful tools for simulation, analysis, and control.

Keywords

Multi-physics systems · Network modeling · Passivity · Compositionality · Interconnection · Nonlinear control

Introduction

Port-Hamiltonian systems theory is rooted in the *port-based modeling* approach to complex multi-physics systems (Paynter 1961), viewing the system as the interconnection of ideal energy storing, energy dissipating, and energy routing elements, via pairs of conjugate variables whose product equals power. It brings together classical Hamiltonian dynamics (originating mostly from mechanics) with network dynamics (motivated in particular by electrical network theory). Thus identifying the underlying physical structure of the (nonlinear) system leads to analysis and control strategies that exploit the nonlinearities and are insightful and often robust.

Port-Hamiltonian Systems

A *port-Hamiltonian system* (briefly, *pH system*), with n -dimensional state space $\mathcal{X}$, input and output spaces $U = Y = \mathbb{R}^m$, and Hamiltonian $H : \mathcal{X} \rightarrow \mathbb{R}$, is defined as (Maschke and van der Schaft 1992; van der Schaft 2017; Ortega et al. 2002; van der Schaft and Jeltsema 2014)

$$\begin{aligned}\dot{x} &= J(x)e - \mathcal{R}(x, e) + G(x)u, \quad e = \nabla H(x) \\ y &= G^T(x)e,\end{aligned}\quad (1)$$

where the $n \times n$ matrix $J(x)$ satisfies $J(x) = -J^T(x)$ for all x , and the mapping $\mathcal{R}$ is such that $e^T \mathcal{R}(x, e) \geq 0$ for all x, e . Here $e = \nabla H(x)$ denotes the n -dimensional column vector of partial derivatives of H . The function H represents the *stored energy* of the system, the matrix J its internal *interconnection structure*, and $\mathcal{R}$ its *energy dissipation structure*. In the case of *linear* dissipation (1) reduces to

$$\begin{aligned}\dot{x} &= [J(x) - R(x)] \nabla H(x) + G(x)u \\ y &= G^T(x) \nabla H(x)\end{aligned}\quad (2)$$

where the $n \times n$ matrix $R(x)$ satisfies $R(x) = R^T(x) \geq 0$ for all x .

The definition of port-Hamiltonian system can be further extended (van der Schaft 2017; van der Schaft and Jeltsema 2014) to include direct feedthrough terms and to mixtures of differential and algebraic equations (DAE systems), as often arise in network modeling of large-scale physical systems. The definition also extends to distributed-parameter physical systems described by partial differential equations; see, e.g., van der Schaft and Maschke (2002).

Passivity and Shifted Passivity

By the properties of $J(x)$ and $\mathcal{R}$, it immediately follows that any pH system satisfies

$$\begin{aligned}\frac{dH}{dt}(x(t)) &= \nabla^T H(x(t)) \dot{x}(t) \\ &= -e^T(t) \mathcal{R}(x(t), e(t)) + y^T(t) u(t) \\ &\leq y^T(t) u(t),\end{aligned}\quad (3)$$

implying *passivity* if H is *bounded from below* (and *cyclo-passivity* for general H). Conversely, it can be shown that most (cyclo-)passive nonlinear systems can be represented as port-Hamiltonian systems for *some* $J(x)$ and $\mathcal{R}(x, e)$. On the other hand, in port-Hamiltonian systems modeling H , J , G , and $\mathcal{R}$, all arise from first principles physical modelling and so have a direct physical interpretation (Duindam et al. 2009; van der Schaft 2017).

In the case of *linear* dissipation, *constant* J, R, G , and *convex* H , port-Hamiltonian systems (2) are also passive with respect to *non-zero* equilibria. Indeed, let $\bar{u}$ be any constant input such that $0 = [J - R] \nabla H(\bar{x}) + G\bar{u}$ for some $\bar{x}$. Then, denoting $\bar{y} = G^T \nabla H(\bar{x})$, (2) can be rewritten as the *shifted* pH system

$$\begin{aligned}\dot{x} &= [J - R] \nabla \hat{H}_{\bar{x}}(x) + G(u - \bar{u}) \\ y - \bar{y} &= G^T \nabla \hat{H}_{\bar{x}}(x),\end{aligned}\quad (4)$$

where the *shifted Hamiltonian* is defined as $\hat{H}_{\bar{x}}(x) = H(x) - \nabla H(\bar{x})(x - \bar{x}) - H(\bar{x})$ (Bregman divergence). By convexity of H it follows that $\hat{H}_{\bar{x}} \geq 0$, thus showing passivity with respect to the shifted inputs and outputs $u - \bar{u}, y - \bar{y}$ (van der Schaft 2017).

Stability Analysis by Energy-Casimir Method

The dissipation inequality (3) implies that H , provided it has a strict minimum at x_0 , can be used as a candidate Lyapunov function for an equilibrium x_0 of the port-Hamiltonian system (1) for $u = 0$. The same applies to non-zero equilibria $\bar{x}$ corresponding to non-zero constant $\bar{u}$ using the shifted Hamiltonian $\hat{H}_{\bar{x}}$. An additional degree of freedom in shaping H (or $\hat{H}_{\bar{x}}$) to a suitable Lyapunov function is offered by the existence of *Casimirs*. These are mappings $C : \mathcal{X} \rightarrow \mathbb{R}^k$ satisfying (in the case of linear dissipation) $\nabla^T C(x) J(x) = 0 = \nabla^T C(x) R(x)$ and thus are *conserved quantities* for the dynamics (2) for $u = 0$. Any $V := H + \Phi(C)$ for $\Phi : \mathbb{R}^k \rightarrow \mathbb{R}$ then satisfies $\frac{d}{dt} V \leq 0$.

Control by Interconnection

A fundamental property of port-Hamiltonian systems is compositionality: power-conserving interconnections of port-Hamiltonian systems are

again port-Hamiltonian. The simplest example is the standard negative feedback interconnection $u_1 = -y_2 + e_1, u_2 = y_1 + e_2$ of two port-Hamiltonian systems (2), indexed by 1, 2, leading to the *closed-loop port-Hamiltonian system*

$$\begin{aligned} \begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} &= \begin{bmatrix} J_1(x_1) - R_1(x_1) - G_1(x_1)G_2^T(x_2) \\ G_2(x_2)G_1^T(x_1) & J_2(x_2) - R_2(x_2) \end{bmatrix} \begin{bmatrix} \frac{\partial H}{\partial x_1}(x_1, x_2) \\ \frac{\partial H}{\partial x_2}(x_1, x_2) \end{bmatrix} + \begin{bmatrix} G_1(x_1) & 0 \\ 0 & G_2(x_2) \end{bmatrix} \begin{bmatrix} e_1 \\ e_2 \end{bmatrix} \\ \begin{bmatrix} y_1 \\ y_2 \end{bmatrix} &= \begin{bmatrix} G_1^T(x_1) & 0 \\ 0 & G_2^T(x_2) \end{bmatrix} \begin{bmatrix} \frac{\partial H}{\partial x_1}(x_1, x_2) \\ \frac{\partial H}{\partial x_2}(x_1, x_2) \end{bmatrix}, \quad H(x_1, x_2) := H_1(x_1) + H_2(x_2) \end{aligned} \quad (5)$$

with inputs e_1, e_2 and outputs y_1, y_2 . Interpreting the pH system indexed by 1 as the *plant system*, and the pH system indexed by 2 as the *controller system*, this leads to the following strategy for, e.g., *stabilization* of a prescribed set-point x_1^* . Design J_2, R_2, G_2 in such a way that one obtains a Casimir $C(x_1, x_2)$ for the closed-loop system, such that for a certain choice of the controller Hamiltonian H_2 and mapping Φ , the function

$$V(x_1, x_2) := H_1(x_1) + \Phi(H_2(x_2), C(x_1, x_2)) \quad (6)$$

has a strict minimum at (x_1^*, x_2^*) for some x_2^* , thus serving as Lyapunov function. Preservation of Casimirs of the special form $C(x_1, x_2) = x_2 - F(x_1)$ implies $x_2 = F(x_1)$ modulo a constant, leading to Lyapunov functions $\tilde{V}(x_1) = H_1(x_1) + \tilde{\Phi}(H_2(F(x_1)))$ in terms of x_1 only, and thus to a *state feedback* interpretation (Ortega et al. 2002; van der Schaft 2017). This can be generalized to *Interconnection-Damping Assignment Passivity-Based Control* (Ortega et al. 2002; Duindam et al. 2009; van der Schaft 2017).

Summary and Future Directions

Port-based modeling of multi-physics systems leads to port-Hamiltonian formulations, bridging the gap between first principles modeling and control. If system parameters or system components are (partly) unknown, this calls

for the development of port-Hamiltonian identification and realization theory. Large-scale systems or spatial discretization of distributed-parameter systems yield high-dimensional port-Hamiltonian system formulations, necessitating structure-preserving model order reduction.

Power System Voltage Stability

Costas Vournas

School of Electrical and Computer Engineering,
National Technical University of Athens,
Zografou, Greece

Abstract

Voltage stability of electric power systems is a challenging topic both theoretically and in practice. This entry touches briefly on the main aspects of the problem and highlights theoretical foundations and fundamental methods for voltage stability analysis. The single-load radial system is used to introduce basic concepts, such as the PV curve, and the instability mechanism, while the implications for a meshed, multiple-load system are briefly outlined. Some applications to practical problems are briefly enumerated.

Keywords

Maximum power transfer · Active and reactive power · Load dynamics · Load tap changers (LTC) · Stability conditions · PV curve

Introduction

Voltage stability is related to the maximum power transfer in an AC (alternating current) network. In normal conditions, system load demand should never come close to this limit. As, however, electricity demand started swelling after the 1970s with an increasingly faster pace, transmission network investments could not follow closely enough. Investment cost in transmission is usually high and difficulties with environmental constraints and “not in my back yard” mentality of local communities did not make transmission network expansion any easier. Power systems are thus relying for their continuing operation more and more on (reactive power) compensation and automatic controls to maintain sufficient transmission capacity of relatively weakening networks.

As a result, several instances of voltage instability started to appear in several industrialized countries after the 1980s (Taylor 1994) leading to smaller or larger area blackouts, much to the surprise of the power engineering community that was not prepared to deal with this type of events, in which a usual and expected phase of gradual voltage decline suddenly precipitates to an uncontrollable voltage drop leading to partial or total blackout after a succession of equipment disconnection by protection devices.

In power system engineering practice, voltage drops following load ramping or sudden events, such as equipment loss (line, generator switching, etc.), usually referred to in power engineering literature as contingencies, are calculated by solving a set of nonlinear algebraic equations known as the power flow problem. As these are “steady-state” equations, the dynamic aspect leading to an accelerating, cascading failure is not obvious. One should notice however in the above account the key word “nonlinear”: nonlinear equations at the maximum power transfer limit no longer have a solution. This was and is one of the keys in understanding the voltage stability problem. To take it one step further, close to the loss of solution (loss of equilibrium), a set of dormant (up to this point) dynamics become dominant

leading the system to instability. The following sections will explain these notions.

Single Generator-Load (Radial) System

Maximum Power Transfer

In any electrical network (DC or AC), there is a maximum power that can be transferred between any two nodes. In a two-node radial system, the maximum power transfer coincides with the well-known impedance matching conditions. For a radial AC system, when the load is restricted to a constant power factor, the impedance matching condition is that the source (network) impedance is equal in magnitude to the load impedance.

Consider the radial system of Fig. 1. In this system we assume that the load active power P (and possibly reactive power Q) is fed through a transformer with adjustable tap ratio r (in per unit). The tap is automatically adjusted by a load tap changer (LTC) so as to keep the secondary voltage V_2 within a deadband. We will consider throughout that the LTC is a part of the load.

The simplest case for this radial system is when both the line and transformer are lossless ($P_G = P_1 = P$) and the load is kept to unity power factor ($Q = 0$). The generator is assumed as a constant voltage source E . If we further assume that the transformer leakage reactance is negligible ($Q_1 = Q = 0$ in Fig. 1), the maximum power transfer in this simple case is encountered when the load impedance, as seen from the primary (r^2/G), is equal to the line reactance:

$$X = r^2/G \quad (1)$$

Power System Voltage Stability, Fig. 1 Single load radial system

where the load conductance $G = P/V_2^2$. It can be readily shown that the maximum power in this case is $P_{\max} = E^2/2X$. Note that this is a static condition that is not related to how the load varies with the voltage V_2 .

The most popular way of visualizing the maximum power condition is through the PV curve of Fig. 2, in which the consumed (transferred) power P is plotted versus the primary (transmission) side voltage V .

In Fig. 2 the nose-shaped solid line is the *network characteristic* corresponding to all possible solution of the network equations for a given P (or V). The maximum power transfer is easily identified as the tip of the curve (point C). Note that PV curves can be plotted for any load power factor and line resistance.

Load Dynamics and Voltage Stability

As stated above, maximum power transfer is a static condition based on network equations only. To identify its relation to voltage stability some form of load dynamics must be introduced. Load dynamics are generally changing the load characteristics so as to adjust load power *consumption* P to a given load *demand* P_o . As a disturbance usually reduces voltage (and thus consumption of a voltage-sensitive load), load dynamics tend to restore the consumption to the pre-disturbance demand.

Load restoration can be continuous, for instance, represented by a time-varying conductance following the ODE:

$$T \dot{G} = \frac{P_o}{V_o^2} - \frac{P}{V_o^2} = \frac{P_o}{V_o^2} - G \left(\frac{V_2}{V_o} \right)^2 \quad (2)$$

Clearly in this case the stability condition is that the consumption $P = GV_2^2$ increases with the increase of the load conductance G :

$$\frac{\partial P}{\partial G} > 0 \quad (3)$$

It is easily verified from Fig. 2 that this condition is met only in the upper part of the PV curve before point C, whereas in the lower part, after point C, increased conductance results in lower

Power System Voltage Stability, Fig. 2 PV curve of radial system

consumption violating (3). Clearly at C (3) holds as an equality.

Assuming the load on the secondary side to be a constant admittance, we can distinguish two types of load characteristics in Fig. 2: the *transient (short-term) load characteristic* shown with dotted lines corresponds to a specific transformer tap ratio r , whereas the *long-term load characteristic* corresponds to equilibrium conditions where V_2 is within the deadband and approximately equal to V_o and is shown with dashed lines for different load demands.

Load dynamics can also be discrete, e.g., driven by the tap changing transformer of Fig. 1. As the LTC is trying to restore the secondary voltage, it will reduce r when $V_2 < V_o - d$ and will increase r when $V_2 > V_o + d$, where d is one half of the deadband.

The effect of tap ratio increase in the upper and lower part of the PV curve is shown in Fig. 2 (points S and U). In the upper part, increased r will reduce consumption which implies that V_2 is also reduced as expected. In the lower part (point U), increased r will increase consumption indicating an increased V_2 and thus an unstable LTC operation. The stability condition in this case is:

$$\frac{\partial V_2}{\partial r} < 0 \quad (4)$$

Clearly for either discrete or continuous dynamics, at the maximum power point C, a stable and an unstable equilibrium branch come together, leaving no equilibrium points for higher demand. In bifurcation theory, this point is known as a saddle-node bifurcation (SNB).

Effect of Generation

The generator behind the constant voltage source E of Fig. 1 supplies the active power consumed by the load (it would cover also active losses, if present). In practice this means that it requires a governor with PI (proportional plus integral) control, as is customary for autonomous systems and a prime mover of the required capacity. The generator also maintains the constant voltage E assumed in the calculations. This requires an automatic voltage regulator (AVR), which can be assumed in this simple example as being also of PI type. The AVR is adjusting the DC rotor (field) current of the synchronous generator so as to maintain the terminal voltage constant.

For a given load, the active and reactive generation $P_G + jQ_G$ required is directly calculated from the network equations. The

electromotive force (EMF) corresponding to the field current can then be determined using standard synchronous machine equations and preferably taking into account the saturation of the machine iron core (Van Cutsem and Vournas 1998). It should be noted that due to thermal constraints, it is not possible to exceed a maximum rotor current in continuous operation. This results in a rotor current limit that is enforced by the generator overexcitation limiter (OEL). If loading conditions are such that the OEL is activated, the generator terminal voltage E cannot be maintained constant, and thus the voltage source E has to be replaced by a constant EMF in series with the generator reactance. This leads to a much more restrictive limit for the maximum power transfer.

In power flow calculations, the generator excitation limit is usually represented by a maximum allowable reactive generation $Q_G^{\max}$. When this limit is reached, the reactive generation remains constant and thus the terminal voltage is allowed to drop, i.e., the generator becomes a PQ bus. Note however that $Q_G^{\max}$ of an actual generator is not constant, but depends on terminal voltage and on active generation.

In any case the overexcitation limit of synchronous generators, and the resulting limitation of the reactive support they offer, are an important factor determining maximum power and thus voltage stability limits. In practice, voltage instability is reached only after some critical generators have reached the overexcitation limit.

Voltage Instability Mechanism

Following the preceding discussion, it is possible to describe the mechanism of voltage instability as follows (Van Cutsem and Vournas 1998):

Voltage instability stems from the attempt of load dynamics to restore power consumption beyond the capability of the combined transmission and generation system.

A voltage instability incident can occur either through a gradual load increase up to the maximum power limit, or most commonly following a contingency (or a cascade of contingencies)

drastically reducing the maximum power transfer below the pre-contingency demand. Thus any attempt at restoring power to the pre-contingency demand will induce an unstable response leading to voltage collapse.

As the load dynamics are the driving force of voltage instability, the time-scale of load restoration is the one characterizing voltage stability. Thus, fast recovering loads, such as induction motors and power electronic-driven devices, tend to restore load in a second or less and constitute what is known in power system dynamic analysis as the short-term time scale (Kundur 2004). Study of relevant problems (motor stalling, delayed post-fault voltage recovery, etc.) is part of *short-term voltage stability* analysis.

In a slower time scale of several seconds up to minutes, load recovery dynamics include the LTCs and thermostatically controlled loads. This is the time-scale of *long-term voltage stability* analysis (Kundur 2004). Note that for long-term voltage stability the short-term dynamics such as those of motors and generators are considered to be at equilibrium. In mathematical system representation, this assumption leads to the replacement of short-term differential equations with algebraic equilibrium equations. This assumption is known as the quasi-steady-state (QSS) approximation.

Multiple-Load (Meshed) System

The single-load system of Fig. 1 serves well in defining the voltage stability problem and helps visualize its significance through the PV curve representation and the maximum loading, or critical point C. In actual power systems, however, there are multiple loads defining a multidimensional space where it is sometimes risky to apply the simple concepts of Fig. 1. For instance, it is important to distinguish between the supply system, which can be represented by a Thevenin equivalent, and the consumption part where loads affect each other and cannot be examined individually, one at a time.

Consider the power system of Fig. 3, where multiple generators are feeding a number of loads

Power System Voltage Stability, Fig. 3 Meshed power system

through a meshed network represented by the complex admittance matrix $\mathbf{Y}$. The steady-state conditions of the system including generation and load are traditionally represented by the power flow equations:

$$\begin{aligned} (P_{Gi} + jQ_{Gi}) - (P_{Ai} + jQ_{Ai}) \\ - \hat{V}_i \sum_{j=1}^N Y_{ij}^* \hat{V}_j^* = 0 \\ i = 1, \dots, N \end{aligned} \quad (5)$$

Using real variables, (5) can be written as:

$$\mathbf{g}(\mathbf{x}, \mathbf{p}) = 0 \quad (6)$$

where $\mathbf{p}$ is the vector of independent parameters (load demands, generator setpoints) and $\mathbf{x}$ the vector of dependent variables (voltage magnitudes and angles, or real and imaginary parts).

Note that in this representation, the load is referred to the primary side of LTC transformers as in Fig. 1. This can be considered constant at long-term equilibrium assuming secondary (distribution side) voltage restoration at its setpoint value $V_{Bi} = V_{oi}$.

Concerning generators the active power P_{Gi} should not be treated as constant when load is varying, so there has to be a participation factor attached to each generator that will represent primary (or secondary) frequency regulation characteristic (Van Cutsem and Vournas 1998). This

is sometimes referred to as *distributed slack bus* approach. For reactive power, the limits $Q_{Gi}^{\max}$ of reactive support should be set, beyond which the generator voltage is no longer constant (switch from PV to PQ bus).

The solution of the N nonlinear complex equations (5) for given load demand determines all complex voltages in the system. As in the simple radial system case, there may exist multiple solutions, some of which are unstable, or no solutions at all. The stability limits, where (3) and (4) hold as equalities for the radial system, are now given by the singularity of the Jacobian of the equilibrium conditions (6):

$$\det \mathbf{D}_{\mathbf{x}} \mathbf{g} = 0 \quad (7)$$

The stability limit can be determined also by the singularity of the state matrix (Van Cutsem and Vournas 1998; Medanic 1987):

$$\det \mathbf{A} = \det \left[\frac{\partial V_i}{\partial r_j} \right] = 0 \quad (8)$$

Note that the impedance matching condition for a single load amounts to the diagonal element of the state matrix becoming zero ($a_{ii} = 0$), which is much more strict than the singularity condition (8) that marks the actual onset of instability. The points satisfying (7) or (8) are critical points and form a multidimensional manifold in parameter space called *bifurcation surface*.

Applications

The above analysis briefly touches on fundamentals. Detailed analysis tools for Voltage Stability include (but are not limited to) continuation power flow, optimal power flow, VQ curves, time simulation (short-term, long-term, QSS), sensitivity and eigenvalue/singular value analysis. Voltage Security Analysis is presently applied on-line in various control centers based on the above methods of analysis for a large number of contingencies. Countermeasures to voltage instability and collapse cover a wide spectrum, from automatic reactive devices switching to special pro-

tection controls and load shedding as a last resort. Further details can be sought in textbooks Taylor (1994) and Van Cutsem and Vournas (1998).

Powertrain Control for Hybrid-Electric and Electric Vehicles

Giorgio Rizzoni

Department of Mechanical and Aerospace Engineering, Center for Automotive Research, The Ohio State University, Columbus, OH, USA

Abstract

Powertrain electrification and hybridization have rapidly become part of the portfolio of all major automotive manufacturers, ranging from hybrid-electric, to plug-in hybrid-electric, to battery-electric vehicles,

to hybrid-hydraulic and hybrid-mechanical solutions. The increased complexity of the powertrain systems associated with hybrid vehicles presents interesting control challenges and problems, and this entry describes the more common architectures of hybrid-electric vehicle powertrains and their operation, focusing on the important problem of optimal control for energy management of hybrid-electric vehicles, on mode switching, and on battery management. In the conclusion, a connection is made between these problems and their interaction with intelligent transportation systems.

Keywords

Battery management · Intelligent transportation systems · Vehicle-grid interaction

Introduction

Increasingly stringent fuel economy and emissions regulations have required the automotive industry to consider more fuel-efficient powertrains and alternative primary sources of transportation fuels. Powertrain electrification and hybridization have rapidly become part of the portfolio of all major automotive manufacturers, ranging from hybrid-electric, to plug-in hybrid-electric, to battery-electric vehicles, to hybrid-hydraulic and hybrid-mechanical solutions. The increased complexity of the powertrain systems associated with hybrid vehicles presents interesting control challenges and problems. This entry describes control problems associated with hybrid-electric vehicles (HEVs) and battery-electric vehicles (BEVs).

HEV Powertrains

An HEV powertrain contains at least two power sources: a primary engine – typically a combustion engine or a fuel cell fueled by a chemical fuel (in liquid or gaseous form) – and a secondary power source that makes use of

Powertrain Control for Hybrid-Electric and Electric Vehicles, Fig. 1 Hybrid powertrain configurations (After Rizzoni and Peng (2013), courtesy: Dr. Chiao-Ting Li, the University of Michigan)

a rechargeable energy storage system (RESS) that permits buffering the power demand of the vehicle so as to provide choices in the use of the power sources. While it is possible to design hybrid powertrains using secondary hydraulic or mechanical energy conversion and storage devices (hydraulic pump/motors and accumulators, mechanical flywheels), the majority of hybrid powertrains in use today employ electric machines and electrochemical energy storage devices (batteries and supercapacitors); thus, this entry focuses exclusively on *hybrid-electric* vehicles (HEVs). Electric vehicles (EVs) can be viewed as a special case of HEVs in which no internal combustion engine is present, and many of the considerations that follow apply also to hydraulic and mechanical

hybrids. HEVs may be classified according to their powertrain architecture as shown in Fig. 1.

A *series HEV powertrain* employs an electric machine (EM) to propel the vehicle while using an internal combustion engine (ICE) coupled to a second EM as an electrical generator set. In a series HEV, the electrical generator set can provide power directly to the electric traction system, via an electrical DC bus, or can charge an RESS (e.g., battery), or can perform both functions. Motive power to the vehicle is delivered by the primary EM. Thus, a series HEV blends electrical power from an RESS with electrical power generated by an ICE-powered generator set to provide motive power to the vehicle. Deciding how much electrical power to draw from

each of the two power sources to meet the power demand of the vehicle is an important control objective. A further feature of interest is the ability to recover some of the kinetic energy of the vehicle during braking events by using the traction EM in generator mode to recharge the RESS.

A *parallel HEV powertrain* blends mechanical power from the ICE and one or more EMs through appropriate mechanical coupling and transmission elements to deliver motive power to the vehicle or to recharge the RESS. In a parallel HEV powertrain, the same EM is used to provide power to the vehicle (motor mode) and to provide energy to the RESS (generator mode); in the latter case, the RESS can be recharged either by providing power from the ICE in excess of that required by the vehicle or by converting the kinetic energy of the vehicle into electrical power through the braking action of the EM.

A third configuration, the one that is most commonly found among passenger vehicles in commercial production today, is the *power-split HEV*, in which the benefits of both series and parallel HEVs are achieved most commonly by using one or more planetary gear sets to couple two EMs – to the ICE on one side and to the driveline on the other.

Regardless of architecture, HEV powertrains enable fuel savings and emissions reductions by operating in a variety of modes that include *load leveling*, *regenerative braking*, *engine start-stop*, and *transmission optimization* (Rizzoni and Peng 2013; Miller 2004). All of these functions benefit from the availability of an RESS and of bidirectional power converters, that is, the electric drive system(s) that can serve both motor and generator functions.

HEV Operation

An HEV is considered *charge sustaining* if the RESS is recharged only by power supplied by the ICE or by regenerative braking. If, on the other hand, the vehicle is designed to deplete energy stored in the RESS during the course of a trip, ending the trip with a lower state of stored energy than at the start and requiring recharging from the

electrical grid, the vehicle is called *charge depleting* and is commonly referred to as a *plug-in HEV* (PHEV). PHEVs can in turn be subdivided into blended-mode PHEVs, in which stored electrical energy and fuel chemical energy are used jointly to achieve minimum overall energy use, and extended-range electric vehicles (EREVs), in which electrical energy is used exclusively to power the vehicle, until a lower bound is reached, at which point the vehicle uses both ICE and EM(s) to behave like a charge-sustaining hybrid. In principle, any of the architectures of Fig. 1 can be used in any of these modes. A battery-electric vehicle, or BEV, is an extreme case of an EREV, in which the vehicle is not equipped with an ICE. Miller (2004) provides an excellent overview of the technology underlying each of the powertrain architectures mentioned so far.

Control Problems in X-EVs

Let us refer to the general case of a hybrid or electric vehicle as an X-EV, with the X in X-EV representing any of the architecture discussed so far: X = H, PH, ER, or B. X-EVs enable multiple configurations and operating modes of the powertrain, presenting a number of interesting control problems above and beyond those that are already present in non-hybrid powertrains (e.g., engine and transmission control). In general, the control architecture of an HEV is hierarchical, with a higher-level (supervisory) controller that manages the power flows and mode changes (e.g., from electric to hybrid in an EREV) to meet the vehicle fuel economy, emissions, performance, and drivability requirements. Figure 2 depicts a hierarchical control architecture in use in a prototype PHEV.

In an X-EV, two problems are especially important: *optimal energy management*, that is, the ability to optimize the energy use of a vehicle during a trip, and *mode switching*, that is, the ability to select the appropriate operating mode and to smoothly switch between modes.

The higher-level controller issues set points to lower-level controllers that are used to

Powertrain Control for Hybrid-Electric and Electric Vehicles, Fig. 2 Hierarchical structure of an HEV controller (Courtesy: The Ohio State University EcoCAR 2 Team)

manage the ICE, the EM(s), the mechanical transmission system, the brake system, and the RESS, as well as other auxiliary functions in the vehicle. In this article we primarily consider the higher-level controller and focus on two problems that are especially relevant to HEVs: *optimal energy management* and *mode switching*. In addition, we also consider the battery controller (often called *battery management system* or BMS), which while being a low-level control is very specific to X-EVs.

Optimal Energy Management

The optimal energy management problem in an X-EV consists of finding the control $u(t)$ that leads to the minimization of a performance index J over the time horizon $t - t_f$, corresponding to a driving cycle, or *trip*; the problem is subject to constraints that are related:

- (i) To physical limitations of the actuators and the energy stored in the RESS
- (ii) To the requirement to maintain the RESS state of energy within prescribed limits (in a charge-sustaining X-EV) or to track a specified RESS stored energy trajectory (in charge-depleting X-EVs)

Let $L(\cdot)$ be a suitable function of the system states and inputs that accounts for the quantities we wish to minimize, for example, fuel consumption or emissions of carbon dioxide. Then, we define the cost function

$$J(x(t), u(t)) = \int_{t_0}^{t_f} L(x(t), u(t), t) dt \quad (1)$$

which is to be minimized for every trip. In general, the exact driving cycle, or profile, associated with a trip is not completely known; thus, a causal solution to this problem is impossible to achieve without making some assumptions. Various approaches to solve (1) have been proposed over the years; we cite (i) dynamic programming (DP), (ii) local optimization solutions as surrogates of a global solution, (iii) Pontryagin's

minimum principle (PMP), and (iv) rule-based methods. Onori et al. (2014) provide a comprehensive overview of the problem as well as detailed examples. We briefly review approaches (i), (ii), and (iii) in the present article.

Global Optimization by Dynamic Programming

If the driving cycle, represented by the vehicle instantaneous velocity over time, $v(t)$ is known, it is possible to cast (1) in such a form that a DP solution is possible. For example, in a charge-sustaining X-EV, one can find the sequence of inputs that minimizes the trip fuel consumption while sustaining the desired state of charge of a battery and meeting the speed profile of the vehicle. In this problem, the input is the power supplied by the battery to the electric machine, and the state of charge of the battery, SOC, is the only state; all other subsystems (engine, electric drives, transmission, etc.) are modeled via quasi-static efficiency models that can be represented by algebraic equations (e.g., Willans lines, Rizzoni et al. 1999) or by maps. The vehicle velocity profile, $v(t)$ is converted to a vehicle power request, $P_{REQ}(t)$, knowing the vehicle load characteristics (aerodynamic, inertial, rolling and drivetrain friction, and road grade). In turn, the power required to meet a specific load profile is the sum of the power delivered by the ICE and EM, $P_{REQ}(t) = P_{ICE}(t) + P_{BAT}(t)$. So, for example, we seek the control input, $P_{BAT}(t)$, that corresponds to the minimum fuel consumption, that is, $\min_{\{P_{ICE}(t), P_{BAT}(t) \forall t\}} \int_{t_0}^{t_f} \dot{m}_f(t) dt$, while delivering the requested vehicle power. The problem has physical constraints in the actuators (maximum and minimum power that can be delivered by ICE and EM), as well as the requirement for the control policy to be charge sustaining, which is translated into the additional condition $SOC(t_0) = SOC(t_f)$. While this is only a sketch of the problem formulation (see Onori et al. (2014) for a detailed treatment), it should be clear that it is possible to find a DP solution. If the

vehicle is charge depleting, the problem can be similarly formulated with $\text{SOC}(t_f) < \text{SOC}(t_0)$.

In practice, this approach requires complete information of the vehicle velocity profile, and DP is not an implementable, causal solution to the X-EV energy management problem. It is, however, a very useful tool to establish a benchmark for a problem or as an aid in developing a rule base (Onori et al. 2014). Stochastic DP methods have been proposed to circumvent the need to know the driving cycle exactly (see, e.g., Tate et al. 2007).

Local Optimization by Equivalent Fuel Consumption Minimization

A heuristic approach that has met with success is to solve (1) as a local optimization problem,

wherein $\int_{t_0}^{t_f} \min_{\{P_{ICE}(t), P_{BAT}(t) \forall t\}} \dot{m}_f(t) dt$ is used as an

approximation for $\min_{\{P_{ICE}(t), P_{BAT}(t) \forall t\}} \int_{t_0}^{t_f} \dot{m}_f(t) dt$.

This approach gives rise to the *Equivalent fuel Consumption Minimization Strategy* (ECMS) (Paganelli et al. 2001), which accounts for the use of stored electrical energy, in units of chemical fuel use (g/s), such that one can define an “equivalent fuel consumption” taking into account the cost of the electrical energy used to produce $P_{BAT}(t)$ by way of the fuel that must be used at a future time to replenish the stored electrical energy in the RESS. The equivalent fuel consumption is defined in (2):

$$\dot{m}_{f,eq}(t) = \dot{m}_f(t) + \dot{m}_{eq}(t) = \dot{m}_f(t) + s(t) \frac{E_{batt}}{Q_{LHV}} \dot{\text{SOC}}(t) \quad (2)$$

In (2), $\dot{m}_{f,eq}$ is the equivalent fuel consumption, $\dot{m}_f$ is the actual chemical fuel consumption, $\dot{m}_{eq}$ is the virtual fuel consumption corresponding to the use of electricity stored in the battery (to be replenished in the future), E_{BAT} is the energy capacity of the battery, Q_{LHV} is the lower heating value of the chemical fuel, and $s(t)$ is the *equivalence factor* that assigns a cost to the use of electricity. Then, the global minimization problem of (1), with $L(\cdot)$ equal to $\dot{m}_{f,eq}$, becomes the

problem of finding $\int_{t_0}^{t_f} \min_{\{P_{ICE}(t), P_{BAT}(t) \forall t\}} \dot{m}_f(t) dt$.

This approach, which can be easily implemented, has been used widely and has been shown to closely approximate the global optimal solution if sufficient knowledge of the vehicle driving cycle is available. The method does require empirical calibration and tuning of the equivalence factor, $s(t)$, the optimal value of which is dependent on the driving cycle. Such calibration could be automated by using a predictor to generate a short-horizon estimate of the driving cycle and an adaptor to generate an appropriate $s(t)$ (Musardo et al. 2005).

Optimization by Pontryagin's Minimum Principle

Pontryagin's minimum principle (PMP) can also be employed to solve the X-EV energy management problem. If, again, the fast dynamics of the system are neglected the state equation is

$$\dot{x}(t) = f(x, u, t) = -\frac{1}{E_{BAT}} I_{BAT}(x, u, t) \quad (3)$$

where $x = \text{SOC}$ is the state of charge of the battery, E_{BAT} is the energy capacity of the battery, and I_{BAT} is the instantaneous battery current. If the input is the power requested of the battery, $P_{BAT}(t)$, which in turn determines the engine power request, $P_{ICE}(t)$, and hence the fuel consumption, then the Hamiltonian function can be defined to be

$$H(x(t), P_{BAT}(t), \lambda(t)) = \dot{m}_f(P_{BAT}(t)) - \lambda(t) \cdot f(x(t), P_{BAT}(t), t) \quad (4)$$

In (4), $f(\cdot)$ is given by Eq. (3), and the control $P_{BAT}(t)$ that which minimizes Eq. (4) at each time instant is

$$P_{BAT}^*(t) = \arg \min_{P_{BAT}} H(x(t), P_{BAT}(t), \lambda(t)) \quad (5)$$

The co-state variable, $\lambda(t)$, is the solution of

$$\dot{\lambda}(t) = -\lambda(t) \frac{\partial f(x(t), u(t))}{\partial x} \quad (6)$$

Eqs. 3 and 5, with boundary conditions $x(t_0)$ and $x(t_f)$, can be solved numerically; in Serrao et al. (2009, 2011) it is shown that the co-state $\lambda(t)$ is related to the *equivalence factor* of Eq. (2), confirming that the intuitive ECMS solution is in fact the PMP solution, providing that the equivalence factor (or co-state) is time varying and satisfies

$$H(t, x, u, \lambda) = \dot{m}_f + \lambda(t)\dot{x}(t) \quad \text{and} \\ s(t) = -\lambda(t) \frac{Q_{LHV}}{E_{BAT}} \quad (7)$$

The PMP solution is also cycle dependent, as the optimal initial condition for the co-state is dependent on the driving cycle. This dependence on the driving cycle, whether expressed in terms of an equivalent fuel consumption in the ECMS solution or as the initial condition of the co-state in the PMP solution, is an unavoidable consequence of the fact that the fuel consumption of a vehicle is strongly dependent on the driving conditions, which affect the vehicle load.

The basic concepts outlined above continue to be the subject of further development; for example, integrating available trip information available from navigation and geographical information systems into predictive energy management algorithms and considering battery aging as a cost in the optimization function are but two of the research areas being pursued.

Mode Switching

X-EV architectures permit multiple operating modes to exploit the design and control flexibility available in the powertrain. Some examples are the following: an X-EV could operate in pure EV mode or in hybrid mode (whether series, parallel, or power-split), could use special control algorithms during regenerative braking events to provide maximum energy recovery without adversely affecting brake and vehicle stability control systems, and could implement special start-stop control strategies that minimize fuel consumption at idle without adversely affecting engine cold- or warm-start emissions and

without inducing unwanted transient vibrations (Canova et al. 2009). Figure 3 depicts an example of a state flow diagram that could be implemented in a finite state machine. Mode switching can result in *drivability* problems (Wei and Rizzoni 2004), that is, in undesirable transient response characteristics during mode changes. An X-EV can, in this context, be represented as a hybrid system (Koprubasi et al. 2007).

Battery Management Systems

The most common RESS in hybrid vehicle is the electrochemical battery. A hybrid or electric vehicle uses a battery pack that is typically composed of modules, which are in turn comprised of battery cells connected in series and parallel. Battery management systems are necessary to provide charge balancing, cell protection, state of charge and state of health estimation, and other functions related to the management of the stored energy. A good overview of battery systems and associated control problems may be found in Rahn and Wang (2013).

Two important problems related to battery management are state of charge (SOC) and state of health (SOH) estimation. SOC estimation is a necessary component of any battery management system. The SOC of battery is defined by the following equations, in which x is the SOC, Q_{BAT} is the battery capacity in ampere-hours, and η is the battery charging/discharging efficiency:

$$\dot{x}(t) = \frac{\eta}{Q_{BAT}(t)} \cdot I_{BAT}(t) \quad x(t) = x(t_0) \\ + \frac{1}{3,600 \cdot Q_{BAT}(t)} \int_{t_0}^{t_f} I_{BAT}(\tau) \cdot d\tau \quad (8)$$

In practice, there are two problems with using current integration (also called *Coulomb counting*) to estimating SOC: (i) errors in numerical integration accumulate and may cause significant bias error in the estimate, and (ii) the actual capacity of the battery is unknown during vehicle operation, as it changes over

Powertrain Control for Hybrid-Electric and Electric Vehicles, Fig. 3 State diagram illustrating mode switching in a PHEV (Courtesy: The Ohio State University EcoCAR 2 Team)

time due to battery aging. A second SOC estimation approach consists of correlating the battery open-circuit voltage to the SOC, but this approach also suffers from significant uncertainty, as the open-circuit voltage-SOC correlation curves are only accurate in stationary conditions (constant temperature, with battery at rest). SOC estimation has been the subject of much research and has seen the use of Kalman filters, extended Kalman filters, particle filters, and other estimation approaches (Chaturvedi et al. 2010).

The SOH of a battery degrades over time due to two principal factors: *capacity fade* and *power fade* (which can also be thought of as *conductance fade* caused by an increase in the internal resistance of the battery). These phenomena are the result of complex electrochemical interactions that are specific to battery chemistry. The ability to estimate the capacity and resistance of a battery during actual operation is a very important aspect of battery management. As in

the case of SOC estimation, no direct measurement is possible outside of controlled laboratory conditions; hence, estimation algorithms must be employed (Chaturvedi et al. 2010). It is important to observe that SOC and SOH estimation algorithms operate on two completely different time scales, as the SOC of a battery fluctuates over time windows of minutes or hours, while the SOH changes very slowly over time, with measurable changes occurring over periods of months or years.

Summary and Future Directions

In summary, the control of X-EV powertrains is a rich subject for control theoreticians and practitioners, presenting topics related to optimization and optimal control (for energy management, battery aging), hybrid control (for drivability), adaptive and predictive control, and estimation. Further, the electrification of

ground vehicles presents interesting opportunities to integrate vehicles with the electric power and communication networks infrastructures. The following paragraphs describe two such opportunities.

Vehicle-Grid Interaction

As the penetration of plug-in vehicles, PHEVs and BEVs, increases, their impact on the electric power grid cannot be neglected; the consideration of increased electric power demand and of the timing of vehicle charging must be included in the control/optimization of the electric power grid.

The electric grid and the transportation system are the two largest sectors that produce greenhouse gas emissions. When large numbers of vehicles are electrified and draw power from the electric grid, it is important to aim for reduced overall greenhouse gas emissions rather than just shifting emissions from tailpipes to power plant stacks. Controlling the charging of plug-in vehicles to alleviate the impact to the grid has been studied, including the idea of using plug-in vehicles as ancillary services to the grid, possibly with significant renewable power sources connected to the grid. Modeling and simulating this integrated system require information on detailed grid load profiles, power generation pricing and carbon emissions, wind statistics, and vehicle usage statistics. In addition, charging control must balance multiple factors: grid stability, fully charging all vehicles, minimizing data collection and communication, and overall system carbon emission minimization.

Intelligent Transportation Systems

X-EVs, as well as conventional vehicles, will benefit from the ability to analyze traffic and geographical information in real time to quantify the effects of infrastructure, environment, and traffic flow on vehicle fuel economy and emissions, and to permit the application of forecasting and optimization methods for energy management (Gong et al. 2011; Wollaeger et al. 2012). There are significant opportunities to achieve significant fuel savings and emissions reduction by considering the large-scale interactions of vehicles with

one another and with the infrastructure, further exploiting the flexibility inherent in X-EVs.

Privacy in Network Systems

Jerome Le Ny

Department of Electrical Engineering and GERAD, Polytechnique Montreal, Montreal, QC, Canada

Abstract

A growing number of large-scale monitoring and control systems enabling a more intelligent infrastructure, such as smart grids and intelligent transportation systems, rely for their operation on private data obtained from individuals or from privacy-sensitive entities more generally. This entry discusses how to capture and enforce formal quantitative privacy constraints to design estimation and control algorithms that can trade off performance for the level of privacy offered. A state-of-the art definition of privacy called *differential privacy*, which provides guarantees against adversaries with arbitrary side information, is presented. It is shown that tools from systems and control can be used to enforce differential privacy guarantees when publishing real-time statistics or solving distributed optimization and control problems based on sensitive data.

Keywords

Data privacy · Differential privacy · Stochastic filtering · Networked systems

Introduction

As real-time prediction, decision, and control technologies increasingly target sensor-rich large-scale *socio-technical* systems, such as intelligent transportation systems or smart grids, new challenges arise to design algorithms that properly interact with and take into account the human component of these systems. The focus of this entry is on the sensing side, where heavy reliance on processing large amounts of detailed data collected from individuals implies that certain privacy constraints must be satisfied, either due to legal requirements or more simply because people tend to value privacy and might refuse to provide their data to overly intrusive and insecure systems.

The development of formal approaches to reason about privacy in data analysis and of mechanisms to embed verifiable privacy-preserving guarantees directly into our algorithms is motivated by the fact that privacy attacks are often difficult to anticipate based on intuition alone. The naive anonymization of microdata (i.e., data directly related to individuals) by removing names and other obvious means of personal identification is generally insufficient, since de-anonymization attacks can be carried out by combining the information contained in the dataset with other sources of information (Sweeney 2002). As another example, consider the fact that the detailed activities of a household can be inferred from the electricity consumption traces collected by smart meters (Hart 1992).

Defining Privacy

In general, privacy-preserving data analysis requires some form of data obfuscation, thereby sacrificing some level of accuracy. Traditionally, various types of “disclosure limitation”

techniques (Duncan and Lambert 1986) have been applied by statisticians and economists when publishing statistics computed from private microdata, such as census data. This includes adding noise, clustering, modifying, and discarding certain parts of the original dataset, but typically does not aim to achieve a formally defined notion of privacy.

Somewhat more recently, several definitions of privacy have thus been proposed, including k -anonymity (Sweeney 2002) and its various extensions, information-theoretic measures of privacy (Sankar et al. 2013), conditions based on observability (Manitara and Hadjicostis 2013), and differential privacy (Dwork et al. 2006). More details can be found in Le Ny (2020, Chapter 1). For example, k -anonymity is aimed at countering re-identification attacks on microdata and constrains the publication of a dataset in such a way that each combination of values for the sensitive attributes occurs in at least k individual records.

Currently the notion of differential privacy is the focus of most of the research in privacy-preserving data analysis. It is motivated by the fact that useful statistical analyses on a dataset result in unavoidable information disclosure about individuals, even those individuals whose data is *not* in the dataset. For example, paraphrasing (Dwork and Roth 2014), a study that links smoking to an increased risk of cancer provides new information about every person known to be a smoker, not just the participants in the study. Hence, differential privacy does not aim to prevent information disclosure per se, as some other approaches, but instead ensures that new inferences cannot be made much more easily about the individuals who participated in a study compared to those who did not.

To introduce the formal definition of differential privacy, fix a probability space $(\Omega, \mathcal{F}, \mathbb{P})$, and let $\mathbf{D}$ be a set of possible datasets of interest, which could be, for example, a set of data tables with a certain structure, or a set of signals. Introduce a (application-dependent) symmetric binary relation on $\mathbf{D}$, called adjacency and denoted Adj . Adjacent datasets might correspond, for example, to adding or removing the record of one

individual. A *mechanism* M is a randomized map with inputs in $\mathbf{D}$, i.e., for any $d \in \mathbf{D}$, $M(d)$ is a random variable with values in some measurable space $(\mathbf{R}, \mathcal{M})$, where $\mathcal{M}$ denotes a σ -algebra on $\mathbf{R}$. Then, M is said to be differentially private if it is hard to distinguish $M(d)$ from $M(d')$ for any two adjacent d, d' (i.e., any $(d, d') \in \text{Adj}$). Concretely, these two random variables should have almost indistinguishable distributions, as captured by the following definition (Dwork et al. 2006).

Definition 1 Let $\epsilon, \delta \geq 0$ be nonnegative scalars. With the above notation, M is said to be (ϵ, δ) -differentially private for Adj (abbreviated (ϵ, δ) -dp) if for all sets $S \in \mathcal{M}$ and all adjacent datasets $(d, d') \in \text{Adj}$, we have

$$\mathbb{P}(M(d) \in S) \leq e^\epsilon \mathbb{P}(M(d') \in S) + \delta. \quad (1)$$

If (1) holds with $\delta = 0$, we say simply that the mechanism is ϵ -differentially private.

In Definition 1, the parameters ϵ and δ characterize the level of privacy, with smaller values for these parameters corresponding to a stronger privacy guarantee, since the distributions of $M(d)$ and $M(d')$ are then closer. Note also that the privacy guarantee offered depends on the choice of adjacency relation, not just ϵ and δ . Hence, if we change the adjacency relation to one that admits more adjacent datasets, it might become more difficult to achieve the same levels ϵ, δ .

An important property of any privacy guarantee is that it should be *resilient to post-processing*, i.e., once a private output is released, it should remain private no matter how one further uses it, as long as the original sensitive data is not re-accessed. For differential privacy, resilience to post-processing corresponds to composing an (ϵ, δ) -dp mechanism with a subsequent 0-dp one to obtain a mechanism that should remain (ϵ, δ) -dp. More generally, we have the following basic composition theorem:

Theorem 1 Let D be a space with an adjacency relation Adj . Let M_1 be an (ϵ_1, δ_1) -dp mechanism on D with values in $\mathbf{R}_1$. Let M_2 be a mechanism on $\mathbf{R}_1 \times D$ such that, for any $r_1 \in \mathbf{R}_1$, $M(r_1, \cdot)$

is (ϵ_2, δ_2) -dp. Then the composed mechanism $M(d) := M_2(M_1(d), d)$ is $(\epsilon_1 + \epsilon_2, \delta_1 + \delta_2)$ -dp. By immediate induction from Theorem 1, the ϵ, δ parameters add when composing any finite number of mechanisms, although this is a generic result providing only an upper bound on these privacy parameters. More refined composition theorems also exist (Dwork and Roth 2014).

Basic Differentially Private Mechanisms

Definition 1 specifies a constraint that a given algorithm should satisfy to be considered private, but not how to achieve this constraint. Since the methods used for differential privacy depend on the applications considered, we now specialize the discussion to datasets consisting of multi-dimensional numeric signals and view mechanisms as (stochastic) dynamic systems transforming these signals. Let $\mathbf{S} := \mathbb{R}^N$ and $\mathbf{S}^m$ represent the set of discrete-time sequences with values in $\mathbb{R}$ and $\mathbb{R}^m$, respectively. For an integer $1 \leq p < \infty$, define the ℓ_p -norm of a signal x in $\mathbf{S}^m$ by $\|x\|_p = (\sum_{t=0}^{\infty} |x_t|_p^p)^{1/p}$, where $|\cdot|_p$ represents the p -norm on $\mathbb{R}^m$, i.e., $|v|_p = (\sum_{i=1}^m |v_i|^p)^{1/p}$, with v_i the i^{th} component of $v \in \mathbb{R}^m$. Two basic mechanisms, the Laplace and the Gaussian mechanism, produce differentially private signals by simply adding an appropriate level of white noise. A standard approach to set the noise level involves the following quantity:

Definition 2 Let $G : \mathbf{S}^n \rightarrow \mathbf{S}^m$ be a system with n inputs and m outputs. Given an adjacency relation Adj on $\mathbf{S}^n$, the ℓ_p -sensitivity of G is defined for $1 \leq p < \infty$ as

$$\Delta_p G = \sup_{(u, u') \in \text{Adj}} \|Gu - Gu'\|_p.$$

In other words, the ℓ_p -sensitivity of a system is a type of incremental gain but for variations in the input restricted to adjacent signals.

The following definitions are needed to introduce the basic mechanisms. The Laplace probability distribution with mean zero and variance

$2b^2$, which has density $\frac{1}{2b} e^{-|x|/b}$ on $\mathbb{R}$, is denoted $\text{Lap}(b)$. We write $X \sim \text{Lap}(b)^n$ to specify that a random vector $X \in \mathbb{R}^n$ has independent and identically distributed (iid) coordinates, all following a $\text{Lap}(b)$ distribution, with corresponding density $\frac{1}{(2b)^n} e^{-|x|_1/b}$ on $\mathbb{R}^n$. The multivariate Gaussian distribution with mean vector μ and covariance matrix Σ is denoted $\mathcal{N}(\mu, \Sigma)$. The Q -function $Q(x) := \frac{1}{\sqrt{2\pi}} \int_x^{\infty} e^{-u^2/2} du$ represents the tail distribution of the standard normal distribution. Since Q is monotonically decreasing, it has an inverse Q^{-1} , which maps the interval $(0, 1)$ into $(-\infty, \infty)$. For $\epsilon > 0$, $1 > \delta > 0$, define the notation $\kappa_{\delta, \epsilon} = \frac{1}{2\epsilon} (Q^{-1}(\delta) + \sqrt{(Q^{-1}(\delta))^2 + 2\epsilon})$.

Theorem 2 Let $G : \mathbf{S}^n \rightarrow \mathbf{S}^m$ be a system with finite ℓ_1 - or ℓ_2 -sensitivity $\Delta_1 G$ and $\Delta_2 G$ with respect to a given adjacency relation Adj on $\mathbf{S}^n$. Then, the mechanism $Mu := Gu + w$, where w is a white noise sequence (iid zero-mean random vectors) such that for all $t \geq 0$, $w_t \sim \text{Lap}(b)^m$ with $b \geq \Delta_1/\epsilon$, is ϵ -dp for Adj . If instead the white noise w is Gaussian with covariance matrix $\sigma^2 I_m$, where $\sigma \geq \kappa_{\delta, \epsilon} \Delta_2 G$, then the mechanism is (ϵ, δ) -dp for Adj .

The Laplace and Gaussian mechanisms of Theorem 2 are already useful by themselves to produce differentially private signals. In particular, if G is the identity operator in Theorem 2, we can typically compute its ℓ_p -sensitivity $\sup_{(u, u') \in \text{Adj}} \|u - u'\|_p$ accurately for reasonable adjacency relations. This gives a simple mechanism, often called the *input perturbation mechanism*, which makes a signal differentially private by simply adding sufficient white noise to it, at the data source, and does not require any knowledge about the computations subsequently performed on the signal, relying instead on the resilience to post-processing property mentioned above Theorem 1. However, much better accuracy can often be achieved by tailoring the noise to the desired computational task specified by a non-trivial system G in the mechanism of Theorem 2, which is then called an *output perturbation mechanism*.

Example 1 Suppose that n individuals produce each a signal $u_i \in \mathbf{S}$, for $1 \leq i \leq n$. The space

D of datasets is $\mathbf{S}^n$. Fix some constant $\rho > 0$ and the adjacency relation

$$\begin{aligned} (u, u') \in \text{Adj} &\iff \exists i \in \{1 \dots, n\} \\ &\text{such that } \|u_i - u'_i\|_2 \leq \rho \\ &\text{and } u_j \equiv u'_j, \forall j \neq i. \end{aligned}$$

Differential privacy for this adjacency relation aims to hide bounded variations in the energy of any single individual's signal. Suppose that an analyst wishes to process the signal u through a stable linear time-invariant (LTI) filter G (with zero initial condition), to obtain an aggregate signal $y = Gu = \sum_{i=1}^n G_i u_i$. In the presence of a differential privacy constraint, a stochastic signal $\hat{y}$ is produced instead. The accuracy of the output can be measured by the steady-state mean squared error (MSE)

$$\lim_{T \rightarrow \infty} \mathbb{E} \left[\frac{1}{T+1} \sum_{t=0}^T |y_t - \hat{y}_t|_2^2 \right]. \quad (2)$$

Suppose for concreteness that we use the Gaussian mechanism. With input perturbation, we have $\hat{y} = G(u + w) = y + \sum_{i=1}^n G_i w_i$, where $w_{i,t} \sim \mathcal{N}(0, \kappa_{\delta, \epsilon}^2 \rho^2)$. The MSE is then the variance of the error term Gw , which is $\kappa_{\delta, \epsilon}^2 \rho^2 \sum_{i=1}^n \|G_i\|_2^2$, where $\|G_i\|_2$ is the H_2 -norm of G_i . On the other hand, for the output perturbation mechanism, we start by computing the ℓ_2 -sensitivity $\Delta_2 G = \max_{1 \leq i \leq n} \sup_{\|u_i - u'_i\|_2 \leq \rho} \|G_i u_i - G_i u'_i\|_2 = \rho \max_{1 \leq i \leq n} \{\|G_i\|_\infty\}$, where $\|G_i\|_\infty$ is the H_∞ -norm of G_i . The signal produced is then $\hat{y} = y + \zeta$, and the MSE is now the variance of ζ , namely, $\rho^2 \kappa_{\delta, \epsilon}^2 \max_i \{\|G_i\|_\infty^2\}$. If all the subsystems G_i are identical, for example, the second expression is independent of n , and hence the performance of the output perturbation mechanism becomes much better than with input perturbation for a sufficient large number of input signals.

Privacy in Network Systems, Fig. 1 Two-stage architecture for differentially private filtering

Differentially Private Filtering

Since the output perturbation mechanism releases signals perturbed by raw white noise, one can expect intuitively that performance could be improved by filtering out this noise. This leads to the two-stage architecture shown on Fig. 1. In this figure, F is the desired filter through which the sensitive signal u should be processed in absence of privacy constraint and G and H are systems to be designed in such a way that the error signal e between the desired output y and the private output $\hat{y}$ is small. Laplace or Gaussian noise w proportional to the sensitivity of G is added according to Theorem 2 to make the signal v differentially private, as well as $\hat{y}$ by resilience to post-processing. Note that the input and output perturbation mechanisms are special cases of this two-stage architecture, taking (G, H) to be (Id, F) and (F, Id) respectively.

Given an adjacency relation on the space of input signals u in Fig. 1 and a choice of sanitization mechanism (adding Laplace or Gaussian noise) to make the signal v private, the filters G and H of the two-stage differentially private mechanism can be designed using the following methodology:

1. Fix a measure of performance to evaluate the quality of a differentially private approximation $\hat{y}$ for a desired signal y .
2. Then, choose a structure for the block H , whose role is to estimate $y = Fu$ based on $v = Gu + w$. Since the block G has not yet been specified at this stage, H is expressed as a function of G .

3. Finally, express the performance measure as a function of G only, and find a system G optimizing this performance.

This methodology has been applied to a number of different scenarios. If nothing is known about the signal u , if adjacent signals differ at a unique time period, and if the performance measure is the MSE, then one can take $H = G^{-1}$ and find the optimal filter G by solving a spectral factorization problem (Le Ny and Pappas 2014). On the other hand, in many cases, some public information is available about the characteristics of u , even though the particular realization that needs to be processed is private. Consider, for example, the following scenarios, for the same adjacency relation:

- If the input signal u is wide-sense stationary with known second-order statistics and G is linear, then one should use a Wiener filter H .
- If moreover the input signal takes discrete values, then a decision-feedback equalizer can be used for H ; see Le Ny (2013).
- If the input signal u is modeled by the output of a linear system and G is linear, then H should be a Kalman filter; see Degue and Le Ny (2017).

Privacy-Preserving Distributed Computations

This section briefly discusses a class of distributed computing, optimization, and control problems subject to privacy constraints. These problems arise, for instance, when a number of agents wish to allocate resources or coordinate decisions in some optimal way but each agent is unwilling to share with the other agents some of the data necessary to set up a standard optimization problem. For example, the cost functions of firms attempting to develop a joint project could provide strategic information to their competitors, or some patients' data necessary to carry out a health-related study might be stored at multiple locations subject to regulations that prevent sharing them.

Consider n agents connected through a communication graph, where the state vector $x_{i,t}$ of agent i at time t is updated through a local rule such as

$$x_{i,t+1} = f_i(x_{i,t}, u_{i,t}, y_{\mathcal{N}_i,t}), \quad 1 \leq i \leq n, \quad (3)$$

where f_i is some function, u_i is a local control input for agent i , $\mathcal{N}_i$ is the set of indices of the neighbors of i in the graph, and $y_{\mathcal{N}_i,t}$ is a vector containing all the messages sent by these neighbors. Each agent generates messages of the form

$$y_{i,t} = g_i(x_{i,t}, v_{i,t}), \quad 1 \leq i \leq n, \quad (4)$$

for some function g_i and some random vector $v_{i,t}$, the latter being used by the agents to protect their private data, which might consist of their state x_i and possibly their local function f_i . Indeed, the agents might want to control their state trajectories in a coordinated manner in order to reach a certain global state or optimize a certain cost function, while keeping part of their individual data private, even though some or all the messages y_i are published, e.g., accessible by a third party monitoring the network.

In the class of distributed computing problems, privacy-preserving average consensus has been studied in several papers. In this case, the agents aim to asymptotically reach a consensus $x_{1,\infty} = \dots = x_{n,\infty} = \frac{1}{n} \sum_{i=1}^n x_{i,0}$ by exchanging messages (4). At the same time, each agent wants to keep its own initial state $x_{i,0}$ hidden, either from an adversary capable of observing all exchanged messages (Huang et al. 2012; Nozari et al. 2017) or from the other agents in the network (Manitara and Hadjicostis 2013; Mo and Murray 2016). The dynamics (3) are typically linear, uncontrolled, and known to all agents, and the individual privacy-preserving noise v_i in (4) needs to be designed. In general, one cannot achieve exact average consensus under a differential privacy constraint, simply because publishing the exact average of a set of private numbers violates differential privacy. Hence, either one must be satisfied with achieving only a randomized approximate average, or another notion of privacy

must be used (Manitara and Hadjicostis 2013; Mo and Murray 2016).

A number of distributed optimization problems have been studied under privacy constraints. For example, Hsu et al. (2016) propose a privacy-preserving primal-dual algorithm for convex optimization, when the global cost and the constraints coupling the agents can be written as sums of individual private functions. The iterations (3) describe each agent implementing a local primal step, using local dynamics f_i known only to this agent and a message y received from a trusted central data aggregator, as there is no direct communication between the agents in this case. After each primal iteration, the agents then send their current local state value to the aggregator performing a dual step updating the dual variables for the coupling constraints, which are then broadcasted back to all agents in the aggregator's message. Since the dual variables depend on the agents' data, privacy-preserving noise is added in this dual step.

Summary and Future Directions

When estimation and control algorithms rely on privacy-sensitive data, the participation of the independent agents providing this data must be encouraged through incentives and data protection guarantees. Formal definitions of privacy can be used to balance privacy costs and system performance improvements in such cases. This entry has discussed in particular how tools from systems and control can be used to design estimators for dynamic systems enforcing differential privacy guarantees, or reason about privacy in distributed computing and control systems. Another relevant and currently active research topic is the privacy-preserving detection of anomalies and abrupt changes in these systems. Significant challenges remain to formulate important privacy-preserving data analysis problems arising in large-scale monitoring and control systems, carefully characterize the achievable performance-privacy trade-offs, or identify the privacy definitions most relevant for different scenarios.

Recommended Reading

Differential privacy is covered in depth in Dwork and Roth (2014). For the privacy-preserving analysis of dynamic datasets, one can find much work using entropy-based definitions of privacy as well as differential privacy in the information theory and signal processing literature; see, for example, the special issue (Trappe et al. 2015). The tutorial paper Cortés et al. (2016) and the monograph Le Ny (2020) provide additional details on the topics discussed in this entry.

Programmable Logic Controllers

Georg Frey
Saarland University, Saarbrücken, Germany

Abstract

The programmable logic controller (PLC) is still the most used automation device in industry. This chapter presents the core concepts of the technology, discusses the software model and programming techniques, and describes the underlying execution model.

Keywords

PLC · IEC 61131 · Ladder diagram

Introduction

Since the 1970s, the programmable logic controller (PLC) has been the primary workhorse of industrial automation. For a long time, it has provided a distinct field of research, development, and application, mainly for control engineering. This area has produced its own design methods and programming languages. Due to its importance for industrial application, a lot of these methods have been standardized by

the International Electrotechnical Commission (IEC). Currently the most influential standards are IEC 61131 (John and Tiegelkamp 2010) and IEC 61499 (Vyatkin 2011). While the latter one is dedicated to distributed systems, IEC 61131 covers the PLC as such. This standard consists of several parts. The most important ones are:

Part 1 : General information. This part covers the *CONCEPT* of PLCs. It describes the general idea and typical functionalities, most importantly, the cyclic processing of the application program working on a stored image of the input and output values.

Part 2 : Equipment requirements and tests. Here requirements on the PLC *HARDWARE* (electrical, mechanical, and functional) and corresponding tests are defined.

Part 3 : Programming languages. This is the most important part of the standard. Based on already existing PLC programming languages, a harmonization of the *SOFTWARE* structure was achieved. This includes a general software model together with a set of different standardized programming languages. IEC 61131-3 paved the way from proprietary programming solutions to a set of well-accepted languages, allowing easier training of PLC programmers and – to some extent – the reuse of application solutions on different hardware platforms.

While Part 2 is of importance for PLC manufacturers only, Parts 1 and 3 contain relevant information for PLC users, especially for designers of PLC control applications. Before discussing these points, the definition of PLC from IEC 61131-1 is reproduced and discussed:

A PLC is a digital electrical system used in manufacturing. It utilizes programmable memory to store practice-oriented control programs. Thus is suitable for implementation of specific functions such as combinatorial control, sequence control, time-, count- and arithmetic functions. Due to its special arrangement of digital or analog input/output, it is used for controlling various machines and processes. (. . .)

This definition is focused on the usage of the device and would – taken out of the context – also cover industrial PCs or microcontroller-based

control solutions. The specifics of PLC hardware are discussed in Part 2 of the standard. However, much more important for distinguishing a PLC from other control hardware are the properties of the execution model described in Part 2 and discussed in the following.

Execution Model

In designing PLC applications, the execution model has to be considered. The main idea is the cyclic execution together with an I/O image. While microcontrollers and PCs typically use an event-based execution model (the application waits for external events from the environment – interrupts – and reacts accordingly), the PLC follows a time-based scheme (the application scans the environment at instances in time, often a fixed cycle time, and reacts on the new status of the input ports).

A PLC cycle consists of three iterated steps: input reading, program execution, and output writing. Together with the concept of the process image – a reserved memory space where input and output variables are stored – this execution model leads to the following:

- (a) During one cycle, input and output values are kept fixed, i.e., a change in input signal values during a cycle will not be seen by the program executed. This means that a temporal change in an input signal value that is shorter than the cycle time may not be registered by the PLC at all.
- (b) Changes in output signal settings by the program will be switched to the actual output ports only after execution of the complete program. This actually means that for an output signal where the value is changed several

times during one program execution, only the last change will be set to the hardware output of the PLC.

- (c) The response time of a PLC, i.e., the time between a change in an input signal and the corresponding reaction at the output port of a PLC, lies between one and two PLC cycles, depending on when the change at the input port occurs relative to the PLC cycle.

While the time needed for input reading and output writing is constant over all cycles, the time for program execution may vary due to conditional execution of some program parts. However, normally the PLC is operated with a fixed cycle time set high enough to allow for the worst-case execution time of the application program.

The advantage of the described concept is the deterministic behavior of the resulting system with a very simple way to determine the timing behavior. This is important for most PLC applications:

- (a) Open-loop control where the reaction to a change of an input signal has to be reached in a limited time, especially in safety-critical applications.
- (b) Closed-loop control where the design of a discrete-time control algorithm is based on the assumption of a fixed sample-time.

To realize control functions, an application program has to be written for the PLC. To this end, Part 3 of the IEC 61131 defines a software model together with a set of programming languages.

Software Model and Programming

The original idea that led to the development of the first programmable logic controller (PLC) in 1968 was to replace hardwired control equipment at machines. Back then, the controllers of machines, for example, lathes or grinders, typically consisted of a cabinet of interconnected relays. The size of such a controller could be considerable, and its failure rate was high due to mechanical defects of single relays. Furthermore, the initial setup was very time-consuming and

error prone, because the relays (often hundreds of them) had to be wired by hand. The biggest drawback of this technology, however, was the problems arising if a controller had to be changed, employing a new function or adjusting to a new production task. Then the hardwired structure had at least partially to be disassembled and rewired. Here was the main advantage of a controller that could be adjusted by changing software instead of hardware.

Since the first PLCs in the early 1970s reached the market, graphical programming methods are used to develop the control algorithms. These are ladder diagram (LD, sometimes also referred to as ladder logic) and later Function Block Diagram (FBD). The implementation of LD on the very first PLC (the Modicon 084) was intended to allow an easy access for the people doing hardwired relay logic until then. (More on the history of PLCs can be found on the website of Dick Morley, commonly known as the father of the PLC (<http://www.barn.org/FILES/historyofplc.html>).)

LD, at least in its early forms, is basically the graphical representation of its hardwired forefather. The name ladder comes from the fact that on both sides of the drawing, there is a power rail, and horizontally between those rails, like rungs on a ladder, sequences of logical element are drawn. The basic of these elements are relays (switches), depending on input signals or internal variables, and coils (memories to store variables and set output signals). The ladder is processed in a top-down and left-right fashion.

Figure 1 shows an example of an LD. Every rung can be read as an IF THEN ELSE statement. The first rung of the ladder means IF (Var1 = 1 AND Var2 = 1) THEN (Var3 := 1; Var4 := 0) ELSE (Var3 := 0; Var4 := 1). The second rung is IF (Var3 = 1 OR Var4 = 0) THEN (Var1 := 1) ELSE (Var1 := 0).

While LD resembles relay logic, FBD is a graphical mimicking of the wiring of simple logic gates, like AND, OR, NOT, or FLIP-FLOP. Both languages (LD as well as FBD) are still part of the IEC 61131-3. However, they are not well suited for the description of sequential and concurrent algorithms because they have no means for the

Programmable Logic Controllers, Fig. 1 Example of a PLC program written in ladder diagram (LD)

visual description of the control flow in a program.

The IEC 61131-3 standard also contains a language that is intended for the graphical description of sequential and concurrent behavior: the sequential function chart (SFC). The SFC is based on Grafcet (David 1995) and represents a form of Petri net (with very special dynamics and functionality). Due to its high functionality, SFC can be easily applied for the structuring of a PLC program on a high level. However, it is cumbersome (and by the standard also not intended) to use for the specification of a low-level sequential algorithm, as, for example, the alternative switching between two motors.

In addition to the three graphical languages, there are also two textual languages in the standard: the assembler-like Instruction List (IL) and the Pascal-like Structured Text (ST).

The decision for one of the languages is based on functional aspects of the application to be realized (high-level languages SFC and ST vs. low-level languages LD, IL, and FBD) but also on traditions in the application domain (e.g., LD in automotive manufacturing vs. FBD in process industry), the geographical region (e.g., LD in the US vs. IL in Germany), and the preferences of the programmer (graphical vs. textual). To allow for flexible solutions and the optimal choice of languages, IEC 61131-3 allows the use of different languages for different parts of the control application.

An application in IEC 61131-3 is structured into Program Organization Units (POUs). Each of the POUs contains a header in a unified syntax for parameter and variable definitions and a body for the actual program code. This body can be written in any one of the defined PLC languages.

There are three types of POU: Program, Function Block, and Function. A program is the top-level POU of a PLC application. Only in a program, variables can be linked to actual input and output ports. A program can call Function Blocks which in turn may call other function blocks. Programs and Function Blocks can also call Functions. A POU of type function has no internal memory, while a Function Block has memory.

IEC 61131-3 introduced the type and instance concept into PLC programming. A Function Block is always the instantiation of a Function Block Type. Each instantiation gets its own name and variable space. This concept is similar to – but much older than – the class-object instantiation idea of object-oriented programming languages. The exclusive use of symbolic variables without direct references to hardware addresses or ports in Function Blocks allows their easy reuse in one or more applications and the definition of widely applicable Function Block (Type) Libraries.

Summary and Future Directions

PLCs are a proven technology in industrial automation. They follow a simple but deterministic execution and software model. This is the main reason why PLCs are still here and will be here for quite some time to come even if there is faster and fancier technology like embedded PCs available.

The current (third) edition of IEC 61131-3 was published in February 2013. In addition to minor corrections, this new edition adds some concepts from object-oriented programming to the existing software model. First tools on the market already support these extensions.

For the future, two trends can be seen. First, there is a growing trend to integrate PLC programming into model-based software development processes, either by generating PLC code from existing model-based toolchains or by integrating model-based approaches, especially from the object-oriented domain into PLC programming environments. Either way this is due to

the fact that the complexity in PLC application is rising, while the development time should be decreased.

Second, there is a growing interest in the use of formal methods in the PLC domain. In recent years, a lot of interdisciplinary work was aimed in this direction. This work results in the formalization of different steps in the control design process depending on what problems are to be solved (Frey and Litz 2000):

1. The demand for reduced development time and the possible reuse of existing software modules result in the need for a formal approach to the development of the PLC programs.
2. The demand for high-quality solutions and especially the application of PLC in safety-critical processes result in the need for validation procedures, i.e., formal methods to prove specific static and dynamic properties of the programs.
3. The large numbers of already installed PLC programs, together with the high expense of programming, lead to the search for verification and validation methods that can be applied directly to programs written in PLC-specific programming languages such as ladder diagram.

To conclude, more than 50 years after its invention, the PLC is still an industrial success story, and due to ever-increasing demands on the complexity and correctness of its applications, it also still provides much room for further research and development.

Pursuit-Evasion Games and Zero-Sum Two-Person Differential Games

Pierre Bernhard
INRIA-Sophia Antipolis Méditerranée, Sophia
Antipolis, France

Abstract

Differential games arose from the investigation, by Rufus Isaacs in the 1950s, of pursuit-evasion problems. In these problems, *closed-loop strategies* are of the essence, although defining what is exactly meant by this phrase, and what is the “Value” of a differential game, is difficult. For closed-loop strategies, there is no such thing as a “two-sided maximum principle,” and one must resort to the analysis of Isaacs’ equation, a Hamilton Jacobi equation. The concept of viscosity solutions of Hamilton-Jacobi equations has helped solve several of these issues.

Keywords

Closed loop strategies · Isaacs’ condition · Viscosity solutions

Historical Perspective

The history of differential games (DG in short) starts with Rufus Isaacs, who coined the phrase in his pioneering work of the early 1950s (Isaacs 1951), which was largely ignored until the publication of his book Isaacs (1965). Through the investigation of particular problems, Isaacs invented by himself (with his own names) the concepts of state and control variables, of feedback, his “tenet of transition” – better known as Bellman’s optimality principle – the (Hamilton-Jacobi-Caratheodory-)Isaacs equation, barriers, some difficult corner conditions (“equivocal lines”), singular arcs (“universal lines”), etc.

Another very early work was Kelendzerize’s chapter “A Pursuit Problem” in the historical book by Pontryagin et al. (1962), but it lacked closed-loop strategies.

John Breakwell and a few followers (Breakwell 1977; Breakwell and Merz 1969) picked up Isaacs’ work where he had left it, still working on particular problems, but adding the power of the computer to analyze the solution of Isaacs’ equation via the structure and singularities of fields of extremal trajectories, while most of the literature concentrated on making precise the concepts of closed-loop strategies and of the Value of the game. Prominent figures in that quest are Krasovskii and Subbotin (1977), Fleming (1961), Friedman (1971), Blaquière et al. (1969), Elliot and Kalton (1972), Emilio and Roxin (1969), and Varaiya and Lin (1969) who together invented the concept of non-anticipative strategies.

The major later innovation was Crandall and Lions’ viscosity solutions of PDEs (Lions 1982; Crandal and Lions 1983) applied to DGs and its Isaacs equation by Evans and Souganidis (1984) and Lions and Souganidis (1985).

We also refer the reader to the entry (Quincampoix 2009) of another Springer Encyclopedia.

General Setup

We shall be interested in (continuous time) two-person zero-sum DGs with complete information, this last phrase meaning that both players know exactly and instantly the state of the system, but (usually) not their opponent's control.

The available space of a short article does not allow us to attempt to give the most general setup of a zero-sum two-person perfect-information differential game. We shall therefore concentrate on a typical class, with a finite dimensional state space, as follows. The data are:

1. A two-player dynamical system with state $x \in \mathbb{R}^n$, control variables $u \in \mathbf{U} \subset \mathbb{R}^\ell$, $v \in \mathbf{V} \subset \mathbb{R}^m$ ($\mathbf{U}$ and $\mathbf{V}$ will often be assumed compact), and its dynamics

$$\dot{x} = f(t, x, u, v), \quad x(t_0) = x_0.$$

$$J(t_0, x_0; u(\cdot), v(\cdot)) = \begin{cases} K(t_1, x(t_1)) + \int_{t_0}^{t_1} L(t, x(t), u(t), v(t)) dt & \text{if } t_1 < \infty, \\ \infty & \text{if } t_1 = \infty. \end{cases}$$

We let

$$G(t_0, x_0; \phi, \psi) := J(t_0, x_0; \Gamma(t_0, x_0; \phi, \psi)).$$

5. A concept of “solution,” where the first player wants to minimize the performance index while the second one wishes to maximize it. (In our choice of definition of J , we have assumed that player one wants over anything else to make the game terminate. If we define J as the integral even for infinite end-time, Isaacs' tenet of transition may not hold.)

If

$$\begin{aligned} & \inf_{\phi \in \Phi} \sup_{\psi \in \Psi} G(t_0, x_0; \phi, \psi) \\ &= \sup_{\psi \in \Psi} \inf_{\phi \in \Phi} G(t_0, x_0; \phi, \psi) = V(t_0, x_0), \end{aligned}$$

then V is called the Value function of the game. Several concepts of upper Value and lower Value may be defined (including the first

Denoting $\mathbf{U}$ and $\mathbf{V}$ the sets of measurable functions from $\mathbb{R}$ to $\mathbf{U}$ and $\mathbf{V}$ respectively, one assumes regularity and growth conditions on f to guarantee existence and uniqueness of the solution $x(\cdot)$ for all (t_0, x_0) and all $(u(\cdot), v(\cdot)) \in \mathbf{U} \times \mathbf{V}$.

2. A termination condition, often given by a target set $\mathcal{T} \in \mathbb{R} \times \mathbb{R}^n$, open or closed according to necessity, defining a final time as $t_1 = \inf\{t \mid (t, x(t)) \in \mathcal{T}\}$. If $\mathcal{T} = \{T\} \times \mathbb{R}^n$, final time is fixed and equal to T . The question of whether there is a finite t_1 is one of central interest in pursuit-evasion games.
3. Sets of admissible closed-loop strategies Φ and Ψ . One should choose them in such a way that replacing (u, v) by a pair $(\phi, \psi) \in \Phi \times \Psi$ in the dynamics always produces a (unique) admissible pair of control functions $(u(\cdot), v(\cdot)) = \Gamma(t_0, x_0; \phi, \psi) \in \mathbf{U} \times \mathbf{V}$.
4. A performance measure, or payoff, typically

and second terms above) that have to coincide for a Value to exist.

Isaacs' Condition In the framework of this short entry, we shall always assume that the game satisfies *Isaacs' condition*. It bears on the *Hamiltonian* $H(t, x, p, u, v) := L(t, x, u, v) + \langle p, f(t, x, u, v) \rangle$ and reads

$$\begin{aligned} & \forall (t, x, p) \in \mathbb{R} \times \mathbb{R}^n \times \mathbb{R}^n, \\ & \inf_{u \in \mathbf{U}} \sup_{v \in \mathbf{V}} H(t, x, p, u, v) \\ &= \sup_{v \in \mathbf{V}} \inf_{u \in \mathbf{U}} H(t, x, p, u, v). \end{aligned} \quad (1)$$

Strategies and Value

In pursuit-evasion games, the concept of closed-loop strategies is of the essence, and

it is extremely important for all DGs. Yet, allowing state feedback strategies such as $u(t) = \phi(t, x(t))$, $v(t) = \psi(t, x(t))$, poses a difficult problem: what classes Φ and Ψ of functions ϕ and ψ to allow? The notations $\inf_{\phi}$ or $\sup_{\psi}$ have no meaning if one does not answer that question. Experience tells us that discontinuous feedbacks are necessary to find the solution of many examples, but then existence, or uniqueness, of the solution of the dynamical equation cannot be guaranteed.

Isaacs' K-strategies were a partial attempt to address this issue. More developed concepts were proposed, from limit of piecewise constant, or piecewise open-loop, controls (Fleming 1961; Friedman 1971) to extensions of the notion of solution of a differential equation (Krasovskii and Subbotin 1977), also proving the existence of a Value. The equivalence of all these Values was an issue until the advent of viscosity solutions of Isaacs' equation.

A tool used to accommodate state-feedback strategies (Bernhard 1977) is

Lemma 1 (Berkovitz) *If $\mathcal{V} \subset \Psi$, then, $\forall \phi$ for which this expression is well defined,*

$$\sup_{\psi \in \Psi} G(t_0, x_0; \phi, \psi) = \sup_{v(\cdot) \in \mathcal{V}} G(x_0, t_0, \phi, v(\cdot)).$$

As a consequence, a saddle-point (ϕ^*, ψ^*) solution is defined by

$$\begin{aligned} \forall u(\cdot) \in \mathcal{U}, \forall v(\cdot) \in \mathcal{V} \\ G(t_0, x_0; \phi^*, v(\cdot)) &\leq V(t_0, x_0) \\ &\leq G(t_0, x_0; u(\cdot), \psi^*), \end{aligned} \quad (2)$$

confronting the closed-loop saddle point strategies to open-loop controls only. (This proves useful in the analysis of Nash equilibria of nonzero-sum DGs.)

Another consequence of Berkovitz' lemma is that if a DG has a saddle point in open-loop controls, it is a saddle point over closed-loop controls as well. (But the existence condition may be less stringent for the later.) The relationship between different forms of the strategies has been

further clarified by Başar (1977) and Başar and Olsder (1982).

As far as the existence of the Value is concerned, the problem for a large class of DGs is solved with *non-anticipative strategies* defined as $\Phi : \mathcal{V} \rightarrow \mathcal{U}$ such that

$$\begin{aligned} \forall t, [\forall s < t \quad v_1(s) = v_2(s)] &\Rightarrow [\phi(v_1(\cdot))(t) \\ &= \phi(v_2(\cdot))(t)], \end{aligned}$$

and likewise for Ψ (notice that for this concept of strategies, (2) is the natural formulation of a saddle point) and with the notion of *viscosity solution of Isaacs' equation*. See Theorem 1 below.

Games of Pursuit Evasion

An important class of DGs is the game of pursuit evasion. Typically, in these games the state x is composed of a sub-vector y of *Pursuer state(s)* and a sub-vector z of *Evader state(s)*. The dynamical function f is separated likewise, the dynamics of the Pursuer depending on the *Pursuer's control(s)* and that of the Evader on the *Evader's control(s)*. Typically, the payoff is time until *capture* defined as $(t, x(t)) \in \mathcal{T}$ (the target is often called *capture set*). This form of DG automatically satisfies Isaacs' condition (1).

Qualitative Game

In pursuit-evasion games, the main issue is to distinguish initial states, called *capturable*, for which a Pursuer's strategy causing finite-time capture against any defense exists, from those, called *safe*, for which the Evader has a strategy guaranteeing *escape* against any defense. This is the topic of the *qualitative game* or *game of kind* (Isaacs). A *theorem of the alternative* is one which states that for a particular (class of) game(s), every initial state is either capturable or safe. Such theorems have been proved for classes of pursuit-evasion games covering essentially all cases of interest, under Isaacs condition (1) with $L = 0$ (Krasovskii and Subbotin 1977; Cardaliaguet 1996; Cardaliaguet et al. 2001).

Capturable states are separated from safe states by a *barrier*, a piecewise smooth manifold which has to be *semipermeable*. This means that for all (t, x) on the barrier where this barrier is a smooth manifold with normal $\nu(t, x)$, it should hold that

$$\begin{aligned} \min_{u \in U} \max_{v \in V} \langle \nu(t, x), f(t, x, u, v) \rangle \\ = \max_{v \in V} \min_{u \in U} \langle \nu(t, x), f(t, x, u, v) \rangle = 0. \end{aligned}$$

A minimax pair $(u, v) = (\hat{\phi}(t, x, v), \hat{\psi}(t, x, v))$ is called a pair of semipermeable strategies. If the boundary of the capture set is a smooth manifold with local outward normal $n(t, x)$, its *usable part* is the region where $\inf_{u \in U} \sup_{v \in V} \langle n(t, x), f(t, x, u, v) \rangle < 0$. The *natural barrier* is a semipermeable manifold constructed backward from its boundary (the BUP), with n as final ν and using the characteristic equations:

$$\dot{x} = f(x, \hat{\phi}, \hat{\psi}), \quad \dot{v}^t = -v^t \frac{\partial f(t, x, \hat{\phi}, \hat{\psi})}{\partial x}.$$

(These trajectories are *abnormal trajectories* of the calculus of variations). In most examples, only part of the manifold thus constructed is a barrier, and the complete barrier is made of manifolds pieced together according to a junction condition insuring that the corners “do not leak” (Breakwell), analogous to the corner conditions of the next section.

Quantitative Game

The quantitative game, or *game of degree* (Isaacs), is played inside the capture zone, typically with time of capture as the payoff. It is ruled by Isaacs’ equation in a fashion similar to that of games of finite duration (see below). Yet, the interplay between the qualitative and the quantitative game may be quite subtle and plays a prominent role in determining the actual capture zone. The Value function is usually discontinuous across other barriers inside the capture zone.

Other Approaches

Other approaches have been developed to solve games of pursuit evasion.

An early approach by Pontryagin (1967), extended by Pshenichnyi (1968), used geometric methods for linear pursuit-evasion games with convex compact control sets. Krasovskii’s *stable bridges* (Krasovskii and Subbotin 1977) are a concept close to Isaacs’ semipermeability. Patsko and Turova (2001) have developed, for some families of DGs, an efficient numerical procedure to compute recursively hypersurfaces of constant time-to-capture, whose discontinuities display the barriers. Cardaliaguet et al. (1999) have developed a theoretical and numerical procedure building on Aubin’s viability theory, which requires less regularity on the data than other approaches.

Provided that care be applied, a quantitative game may be transformed into a family of qualitative games – an approach used by Krasovskii, Blaqui  re et al., and Cardaliaguet et al. – and conversely, a fruitful approach is to investigate capturability of initial states as a function of a parameter defining the “size” of the capture set, imbedding the qualitative game into a quantitative game of the type *game of approach*.

Games of Finite Duration

Wherever termination of the game is not an issue, the major tool in investigating a DG is Isaacs’ equation, a partial differential equation bearing on the Value function:

$$\begin{aligned} \forall (t, x) \notin \mathcal{T}, \quad \frac{\partial V}{\partial t}(t, x) \\ + \min_{u \in U} \max_{v \in V} H(t, x, \nabla_x V, u, v) = 0, \\ \forall (t, x) \in \mathcal{T}, \quad V(t, x) = K(t, x). \end{aligned} \quad (3)$$

For any DG where all trajectories are transverse to the boundary $\partial \mathcal{T}$, and with adequate regularity conditions on the data (and still under condition (1)), it holds that

Theorem 1 *The DG has a Value in non-anticipative strategies, which is the only bounded,*

uniformly continuous viscosity solution of the equation obtained by changing signs in (3) as $-\partial V/\partial t - \min_{u \in U} \max_{v \in V} H = 0$. And all other Values coincide.

One possible way to solve Isaacs' equation is via the investigation of its field of characteristics. Their equations are Isaacs' *retrograde path equations*: let $(\hat{u}, \hat{v}) = (\hat{\varphi}(t, x, p), \hat{\psi}(t, x, p))$ be the saddle point of $H(t, x, p, u, v)$, assumed here to be unique, one integrates from the target set backward:

$$\dot{x} = f(t, x, \hat{u}, \hat{v}), \quad (4)$$

$$\dot{p} = - \left(\frac{\partial H(t, x, p, \hat{u}, \hat{v})}{\partial x} \right)^t. \quad (5)$$

The above equations are similar to Pontryagin's maximum principle equations. However, a major difference lies in the *corner conditions*. While Pontryagin's theorem extends to control theory the Erdman-Weierstrass condition stating that the adjoint vector (here p) is continuous along an extremal trajectory, in (4) and (5), p is to coincide with $\nabla_x V$ and **may be discontinuous along an extremal trajectory**. These discontinuities cannot be found by a local analysis along an isolated trajectory and require that a complete field of extremals be constructed, synthesizing a state feedback strategy.

The analysis of the conditions that hold at such corners, equivocal manifolds (Isaacs), envelope manifolds (Breakwell), and focal manifolds (Merz), has been a large part of the early Isaacs-Breakwell theory. It has been for its larger part synthesized by Bernhard (1977), except a general constructive analysis of focal manifolds which had to wait until Melikyan and Bernhard (2005).

The absence of a "two-sided Pontryagin principle" for closed-loop differential games forces one to resort to the solution of Isaacs' equation or an equivalent. This is the reason why no practical method of solution exists beyond a state dimension of 3 or 4, counting time if the game is not time invariant. An exception is the linear quadratic game. (See article ► [Linear Quadratic Zero-sum Two-person Differential Games](#) in this encyclopaedia).

Conclusion

Except for very particular games, "solving" a DG remains a difficult task. Numerical methods suffer the famous "curse of dimensionality." Moreover, many of them strive to compute the Value function. But the optimal strategies typically depend on the gradient of the Value function, requiring a stronger convergence of the approximation algorithms than pointwise, or C^0 or L^2 , if they are to be computed as well. Further advances in numerical algorithms tackling this problem would be useful, as well as uncovering new classes of DGs for which further analytical results could be obtained.

Q

Quantitative Feedback Theory

Mario Garcia-Sanz
Case Western Reserve University, Cleveland,
OH, USA

Abstract

Designing reliable and high-performance control systems is an essential priority of every control engineering project. In many practical situations, the presence of model uncertainty challenges the design. A robust control approach for these cases, deeply rooted in the classical frequency domain, is the *Quantitative Feedback Theory* (QFT). As an intrinsically multi-objective methodology, QFT is able to design control solutions that guarantee the achievement of a multi-objective set of performance specifications for every plant within the model uncertainty. It gives the control engineer a physical understanding of the trade-offs, limitations, and possibilities of the control system at every step of the design process, balancing also the trade-off between the simplicity of the controller structure and the minimization of the control activity at each frequency of interest. Control solutions designed by the QFT

methodology reach from simple P, PI, or PID (proportional, integral, derivative) structures to much more complex high order and multi-block/multivariable structures. QFT has a proven track record of success in an extensive variety of real-world control problems, including linear and nonlinear plants, stable and unstable systems, multi-input multi-output processes, minimum and non-minimum phase plants, containing time-delay, lumped and distributed parameters, and advanced control topologies. Recent developments on computer-aided design tools facilitate the use of QFT to the control engineer.

Keywords

Robust control · Quantitative feedback theory · Frequency domain control

Acronym

QFT

Definition

Quantitative Feedback Theory (QFT) is a robust control engineering methodology that uses feed-

back to simultaneously (1) reduce the effects of *plant uncertainty* and (2) satisfy *stability and performance control specifications*. As an intrinsically multi-objective methodology, QFT designs control systems that quantitatively guarantee the satisfaction of all the required control specifications for all the plants within the associated model uncertainty (*robust control*).

QFT is rooted in the classical *frequency domain*. It deals with Bode diagrams and Nichols charts (magnitude/phase diagrams). It relies on the observation that a system needs feedback control when (1) the plant contains model uncertainty and/or (2) external unknown disturbances affect the plant. QFT balances quantitatively (a) the complexity of the controller structure, (b) the minimization of the so-called cost of feedback – controller magnitude at each frequency, (c) the plant model uncertainty, and (d) the achievement of all the required control specifications, all at each frequency of interest. QFT has a proven track record of success in an extensive variety of real-world control problems.

Historical Notes

Hendrik Bode established many of the frequency domain fundamentals in his seminal book *Network Analysis and Feedback Amplifier Design* (Bode 1945). The book strongly influenced the understanding of automatic control theory, especially where system's sensitivity and feedback constraints are concerned.

Almost 20 years later, Isaac Horowitz wrote another very influential book entitled *Synthesis of feedback systems* (Horowitz 1963). The book proposed for the first time a formal combination of frequency-domain control design methodologies and plant model uncertainty (*robust control*) under a quantitative analysis. It addressed numerous sensitivity problems in feedback control, being also the first work in which a control problem was treated quantitatively in a systematic way. The book laid the foundation for a new control design methodology that had been

introduced briefly in a previous paper by Horowitz in 1959. This new methodology became known as *Quantitative Feedback Theory* (or QFT) in the early 1970s.

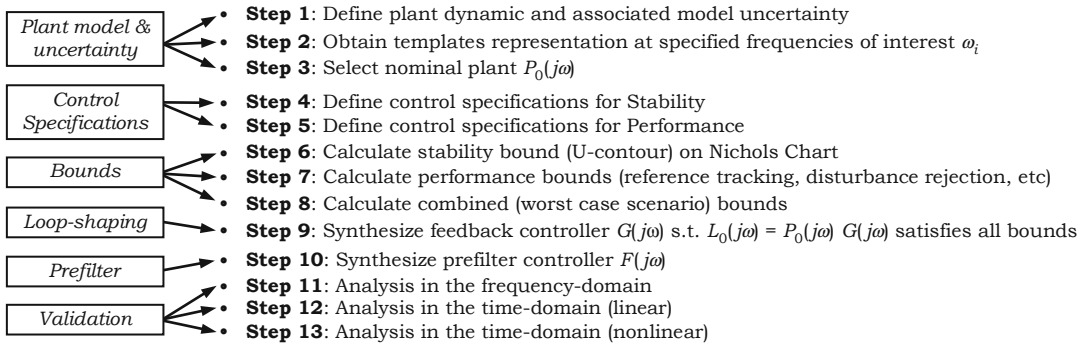

Fundamentals

A detailed study of the *QFT fundamentals and applications* can be found in the books written by Garcia-Sanz (2012, 2017), Houpis (2006), Sidi (2002), Yaniv (1999), and Horowitz (1993) – see recommended reading.

QFT gives the control engineer a comprehensive and physical understanding of the trade-offs, limitations, and possibilities of the control system at every step of the design process. It quantifies the balance among (1) the complexity/simplicity of the controller structure, (2) the multi-objective performance specifications, (3) the plant model uncertainty, and (4) the cost of feedback, all at each frequency of interest. Control solutions designed by the QFT methodology reach from simple P, PI, or PID (proportional, integral, derivative) structures to much more complex high order and multi-block/multivariable structures. The basic steps of the QFT methodology are summarized in Fig. 1 and are introduced in the following subsections.

Define Plant Dynamics, Model Uncertainty, and QFT Templates (Steps 1, 2 and 3)

The QFT methodology starts by modeling the dynamics of the plant and the associated model uncertainty. This step requires an engineering understanding of the system and typically involves multi-physical models, Euler-Lagrange methods, differential equations, state-space representations, and other techniques – see case studies in Garcia-Sanz (2017). Once the mathematical description of the system is obtained, it is translated into a transfer-function representation with block diagrams, parametric/nonparametric uncertainty, and model structure uncertainty. This representation contains the frequency domain

Quantitative Feedback Theory, Fig. 1 Summary of QFT controller design methodology

information ($s \approx j\omega$) and is used to easily calculate the so-called QFT “templates”, which are sets of complex numbers at each frequency of interest $\omega \in [\omega_{\min}, \omega_{\max}]$ rad/second: a projection of the n -dimensional parametric-space through the transfer function(s) onto the Nichols chart.

As an example and for “ $\omega = 1$ rad/s, Fig. 2b represents the QFT template of the 3-parameter plant $P(j\omega) = \exp(-j\omega\tau) / ((j\omega)^2 + 2\zeta\omega_n(j\omega) + \omega_n^2)$, with $\omega_n \in [0.7, 1.2]$, $\tau \in [0, 2]$, and $\zeta = 0.02$.

Each template $\mathfrak{P}(j\omega_i) = \{P(j\omega_i)\}$ represents all the possible plants within the model uncertainty, on the Nichols chart and at a given frequency ω_i (Fig. 2c). A particular case, defined as a set of specific parameters of the n -dimensional parameter space, is arbitrarily selected to define the nominal plant $P_0(j\omega)$, a member of the family of plants within the uncertainty (Fig. 2b).

$U(j\omega)$, $Y(j\omega)$, $D(j\omega)$, and $N(j\omega)$ are signals representing, respectively, the reference input to follow, the signal error, controller output, plant output, disturbance input, and sensor noise input. Using a simple block diagram algebra, the following equations are easily calculated (note that the dependency on $s \approx j\omega$ is removed to simplify the notation):

$$\begin{aligned}
 Y &= \frac{P G}{1 + P G H} F R + \frac{M}{1 + P G H} D \\
 &\quad - \frac{P G H}{1 + P G H} N; \\
 U &= \frac{G}{1 + P G H} F R \\
 &\quad - \frac{G H}{1 + P G H} (M D + N) \quad \text{and} \\
 E &= \frac{1}{1 + P G H} F R - \frac{H M}{1 + P G H} D \\
 &\quad - \frac{H}{1 + P G H} N
 \end{aligned}$$

Define Control Specifications (Steps 4 and 5)

A standard two degree of freedom (2DOF) control system diagram is shown in Fig. 3. It includes the set of uncertain plants $P(j\omega)$ to be controlled, the disturbance dynamics $M(j\omega)$, and the feedback path dynamics $H(j\omega)$. It also shows the loop controller $G(j\omega)$ and the prefilter $F(j\omega)$, both to be designed. In addition, $R(j\omega)$, $E(j\omega)$,

Based on these expressions, the *stability and performance specifications* can now be defined by choosing $\delta_k(\omega)$ functions that limit the magnitude of the transfer functions $T_k(j\omega)$ that appear in these equations, being $|T_k(j\omega)| \leq \delta_k(\omega)$, $k = 1, 2, \dots$, over different frequencies of interest ($\omega \in \Omega_k$) for each specification – see section 2.15 in Garcia-Sanz (2017).

Quantitative Feedback Theory, Fig. 2 From the parameter space to the Nichols chart: (a) two-dimensional parameter space, (b) template of the plant $P(j\omega)$ at $\omega = 1 \text{ rad/s}$, and (c) typical templates for frequencies $\omega \in [\omega_{\min}, \omega_{\max}]$

Quantitative Feedback Theory, Fig. 3
Multi-Input-Single-Output 2DOF feedback control system. $s \approx j\omega$

Stability and noise reduction: $|T_1(j\omega)| = \left| \frac{Y(j\omega)}{R(j\omega)F(j\omega)} \right| = \left| \frac{Y(j\omega)}{N(j\omega)} \right| = \left| \frac{P(j\omega)G(j\omega)}{1+P(j\omega)G(j\omega)} \right| \leq \delta_1(\omega), \quad \omega \in \Omega_1,$

Disturbance rejection: $|T_2(j\omega)| = \left| \frac{Y(j\omega)}{D(j\omega)} \right| = \left| \frac{M(j\omega)}{1+P(j\omega)G(j\omega)} \right| \leq \delta_2(\omega), \quad \omega \in \Omega_2,$

Control effort reduction: $|T_3(j\omega)| = \left| \frac{U(j\omega)}{M(j\omega)D(j\omega)} \right| = \left| \frac{U(j\omega)}{N(j\omega)} \right| = \left| \frac{U(j\omega)}{R(j\omega)F(j\omega)} \right| = \left| \frac{G(j\omega)}{1+P(j\omega)G(j\omega)} \right| \leq \delta_3(\omega), \quad \omega \in \Omega_3$

Reference tracking: $\delta_{4\inf}(\omega) < |T_4(j\omega)| = \left| \frac{Y(j\omega)}{R(j\omega)} \right| = \left| F(j\omega) \frac{P(j\omega)G(j\omega)}{1+P(j\omega)G(j\omega)} \right| \leq \delta_{4\sup}(\omega), \quad \omega \in \Omega_4,$

$$\frac{|G(j\omega)P_d(j\omega)|}{|G(j\omega)P_e(j\omega)|} \frac{|1+G(j\omega)P_e(j\omega)|}{|1+G(j\omega)P_d(j\omega)|} \leq \delta_4(\omega) = \frac{\delta_{4\sup}(\omega)}{\delta_{4\inf}(\omega)}, \quad \omega \in \Omega_4$$

Note that without losing generality and with a straightforward block diagram manipulation, the previous expressions have been rearranged to have a unitary $H(s)$.

QFT Bounds (Steps 6, 7 and 8)

Once the calculations of the previous steps are ready, the QFT methodology combines the stability and performance specifications $\delta_k(\omega)$, the plant model and associated uncertainty, and the selected nominal plant $P_0(j\omega)$ into a set of iso-lines or bounds on the Nichols chart for each frequency of interest (the *Horowitz-Sidi Bounds*).

In particular, the ω_i plant template, $\Im P(j\omega_i) = \{P(j\omega_i)\}$, is approximated by a finite set of plants $\{P_r(j\omega_i), r = 1, 2, \dots\}$, where each plant is expressed in its polar form as $P_r(j\omega_i) = p(\omega_i) \exp(j\theta(\omega_i)) = p \angle \theta$. Similarly, the controller is expressed in its polar form as $G(j\omega_i) = g(\omega_i) \exp(j\phi) = g \angle \phi$, with a controller phase ϕ that varies from -2π to 0 rad. With these representations, and for every frequency ω_i , the control specifications $\{|T_k(j\omega_i)| \leq \delta_k(\omega_i), k = 1, 2, \dots\}$ are translated into a set of quadratic inequalities with the format $I_{\omega_i}^k(p, \theta, \delta_k, \phi) = a g^2 + b g + c \geq 0$, such that,

$$\text{Stability and noise reduction: } p^2 \left(1 - \frac{1}{\delta_1^2}\right) g^2 + 2 p \cos(\phi + \theta) g + 1 \geq 0,$$

$$\text{Disturbance rejection: } p^2 g^2 + 2 p \cos(\phi + \theta) g + \left(1 - \frac{m^2}{\delta_2^2}\right) \geq 0, \text{ with typically } m = p, 1, \text{ or other options,}$$

$$\text{Control effort reduction: } \left(p^2 - \frac{1}{\delta_3^2}\right) g^2 + 2 p \cos(\phi + \theta) g + 1 \geq 0, \text{ and}$$

$$\text{Reference tracking: } p_e^2 p_d^2 \left(1 - \frac{1}{\delta_4^2}\right) g^2 + 2 p_e p_d \left(p_e \cos(\phi + \theta_d) - \frac{p_d}{\delta_4^2} \cos(\phi + \theta_e)\right) g + \left(p_e^2 - \frac{p_d^2}{\delta_4^2}\right) \geq 0$$

Subsequently, with an appropriate algorithm – see section 2.7 in Garcia-Sanz (2017), the above quadratic inequalities are easily translated into a set of curves on the Nichols chart for each frequency of interest and type of specification: the *individual specification*

bounds. Then, the more demanding (worst case) bound, i.e., the most restrictive one at every phase and each frequency of interest, is selected to obtain the intersection of bounds, or the *combined QFT bounds* (see B_i lines in Fig. 4a).

Controller $G(j\omega)$ Design: Loop Shaping (Step 9)

Designing a controller for an infinite number of plants (models with uncertainty) and a set of multi-specification objectives seems to be a very arduous task. However, QFT significantly simplifies this job by combining all these information in a set of simple curves: the QFT bounds. As a result, the designer can use just only a single plant, the already selected nominal plant P_0 , and compare it with the QFT bounds to design the controller.

In this design stage, also called loop shaping, the controller $G(j\omega)$ is synthesized on the Nichols chart by adding poles and zeros until the nominal loop, defined as $L_0(j\omega) = P_0(j\omega)G(j\omega)$, lies near its bounds. This is

achieved when for each frequency of interest, represented by a given color, the corresponding small circle in L_0 lies near its bound, which is denoted by the corresponding B_i line of the same color (Fig. 4a). As mentioned, these QFT bounds represent the plant models with uncertainty and the performance specifications at each frequency. An optimal controller in the sense of QFT will be obtained if $L_0(j\omega)$ (circles) lies exactly on these bounds (B_i lines) at each frequency. Practically speaking, a good design will place $L_0(j\omega)$ above the continuous line B_i bounds and below the dashed line B_i bounds and will have the minimum possible magnitude at every frequency. A general formulation for the controller structure $G(s)$ is expressed by the following transfer function:

$$G(s) = k_G \frac{\prod_{i=1}^{n_{rz}} \left(\frac{s}{z_i} + 1 \right) \prod_{i=1}^{n_{cz}/2} \left(\frac{s^2}{|z_i|^2} + \frac{2 \operatorname{Re}(z_i)}{|z_i|^2} s + 1 \right)}{s^r \prod_{j=1}^{m_{rp}} \left(\frac{s}{p_j} + 1 \right) \prod_{j=1}^{m_{cp}/2} \left(\frac{s^2}{|p_j|^2} + \frac{2 \operatorname{Re}(p_j)}{|p_j|^2} s + 1 \right)}$$

where k_G is the controller gain, z_i is a zero (real or complex) with m_{rz} and m_{cz} the number of real and complex zeroes, respectively, and p_j is a pole (real or complex) with m_{rp} and m_{cp} the number of real and complex poles, respectively (m_{cz} and m_{cp} even numbers). The controller may have also some poles at the origin (integrators), with $r = 0, 1$ or 2 , etc. For practical tips to design the controller (loop shaping), see section 2.15 in Garcia-Sanz (2017).

Prefilter $F(j\omega)$ Design (Step 10)

If the feedback system includes a reference tracking problem, then the best choice is to use a prefilter $F(s)$ – the second degree of freedom. While the feedback controller $G(s)$ reduces the effect of the uncertainty and improves stability, disturbance rejection, and other specifications, the prefilter $F(s)$ is designed to achieve some required reference tracking objectives. Figure 4b shows a typical prefilter design in the Bode diagram. $\delta_{4\sup}(\omega)$ and $\delta_{4\inf}(\omega)$ are the reference tracking

specifications, defined as a band in the frequency domain (outer dashed lines in Fig. 4b), which correspond to upper and lower limits of the plant output in the time domain, $\delta_{4\sup}(t) \geq y(t) \geq \delta_{4\inf}(t)$, when an input reference is applied. In this case, the transfer function T_4 shows an upper and a lower limit (inner gray dashed lines, Fig. 4b) due to the plant uncertainty. After an appropriate prefilter design, the T_4 limits will be inside the $\delta_{4\sup} - \delta_{4\inf}$ band:

$$\delta_{4\inf}(\omega) \leq |T_4| \leq \delta_{4\sup}(\omega),$$

$$\begin{aligned} |T_4(j\omega)| &= \left| \frac{Y(j\omega)}{R(j\omega)} \right| \\ &= \left| \frac{P(j\omega) G(j\omega)}{1 + P(j\omega) G(j\omega)} F(j\omega) \right| \end{aligned}$$

Validation (Steps 11, 12, 13)

Once the design of the controller (and prefilter if needed) is finished, it will be convenient to analyze the performance of the complete control system under different scenarios. This includes

Quantitative Feedback Theory, Fig. 4 (a) QFT-bounds $B_i(\omega)$ and loop shaping $L_0(j\omega) = P_0(j\omega)G(j\omega)$. (b) Prefilter $F(j\omega)$ design: reference tracking specifications

(a) frequency-domain analysis of each specification for all the significant plants within the model uncertainty and (b) time-domain simulations, typically using a Monte Carlo campaign for the uncertainty, first with the linear system and then with nonlinear elements (saturation, etc.).

Programs and Data

Computer-aided design tools facilitate the use of QFT. The most recent QFT control toolbox for Matlab developed by Garcia-Sanz can be found at <http://codypower.com/CDP-QFTCT.htm>. Another popular QFT tool, developed in the 1990s by Borghesani, Chait, and Yaniv, can be found at <http://www.terasoft.com/products/QFT/index.html>.

Applications and Future Directions

- QFT has been successfully applied to an extensive variety of control problems, including stable and unstable plants minimum and non-minimum phase systems, single-input single-output and multiple-input multiple-output processes, with linear and nonlinear characteristics, long time delay,

$\delta_{4sup}(\omega)$ and $\delta_{4inf}(\omega)$, and upper and lower limits of T_4 due to the plant uncertainty: $\delta_{4inf}(\omega) \leq |T_4| \leq \delta_{4sup}(\omega)$

distributed parameter systems, and time-varying plants, and has been combined with feedforward control topologies, multi-loop systems, etc. In addition, QFT has been used in many real-world applications, including flight control, wind energy, water treatment plants, spacecraft, power systems, mechanical systems, motion control, chemical reactors, etc. – see Garcia-Sanz (2017).

- Future research on QFT includes new multiple-input multiple-output techniques, nonlinear control, distributed parameter systems, load-sharing control, multi-agent systems, etc.

Quantized Control and Data Rate Constraints

Girish N. Nair

Department of Electrical and Electronic Engineering, University of Melbourne, Melbourne, VIC, Australia

Abstract

This entry briefly describes the topic of quantized control with limited data rates. The focus is on the problem of stabilizing a linear time-invariant plant over a digital channel and the associated *data rate theorems*. It is shown that the deepest results in this area require a unified treatment of its communications and control aspects.

Keywords

Quantized control · Quantization · Control under communication constraints

Introduction

One of the standard assumptions of classical control theory is that the signals sent from sensors to controllers and from controllers to actuators take continuous values with infinite precision. The advent of computer-based and digitally networked control systems challenged this assumption, since the analog plant outputs or control variables in such systems must be reduced to finite bit strings or discrete symbols for storage, manipulation, and transmission. This process of converting a continuous-valued variable into a finite-valued one is called *quantization* and entails a potentially significant loss of resolution and closed-loop performance. Quantized control is concerned with the analysis and design of control systems which feature such analog-to-digital conversions in the feedback loop.

There is a vast literature on this topic, and the aim of this entry is to briefly explain some of its key ideas. For reasons of space, the discussion is largely confined to the question of how to stabilize a linear time-invariant plant over a digital channel. It is shown that the deepest results here emerge from treating the communications and control aspects jointly, instead of separately. The reader is referred to the survey (Nair et al. 2007) and the references therein for a discussion of other issues such as optimality and transient performance.

Quantization

Quantization has long been an object of study in communications and information theory – see Gersho and Gray (1993) and the references therein. In its simplest form, a signal $x(\cdot) : \mathbb{R} \rightarrow \mathbb{R}^n$ is first *sampled* at regular time intervals $t = 0, \tau, 2\tau, \dots$ to yield a discrete-time signal $(x(k\tau))_{k \in \mathbb{Z}}$, with the sampling frequency $1/\tau$ chosen to be greater than the Nyquist frequency of x (i.e., twice its bandwidth). Each sample $x_k := x(k\tau)$ is then passed through a static, memoryless quantizer Q to yield a quantized discrete-time signal

$$x_k^q = Q(x_k) \in \{q^1, \dots, q^M\} \subset \mathbb{R}^n, \quad k \in \mathbb{Z}_{\geq 0}. \quad (1)$$

which can take M distinct values in $\mathbb{R}^n$. If the quantizer is known to both transmitter and receiver, each of these M values can be represented by a binary string with $\lceil \log_2 M \rceil$ bits. When the input dimension $n = 1$, the quantizer is called scalar; otherwise, it is a vector quantizer. The regions $R^i := Q^{-1}(q^i)$, $1 \leq i \leq M$, are called the quantizer cells and together form a partition of $\mathbb{R}^n$. Thus an M -valued quantizer is fully defined by its quantizer cells R^i and associated quantizer points q^i , $1 \leq i \leq M$.

The quantization error or *quantizer noise* is defined as $n_k := x_k^q - x_k$. When the inputs x_k are identically distributed random variables (rv's), then a standard goal is to design Q so as to minimize the mean-square quantizer noise

$$D := E[||Q(x_k) - x_k||^2], \quad (2)$$

where $E[\cdot]$ is the expectation functional. This yields an optimal quantizer Q_* with cells that satisfy the nearest-neighbor property, i.e.,

$$x \in R_*^i \Rightarrow ||Q_*(x) - q_*^i|| \leq ||Q_*(x) - q_*^j||, \quad \forall j \neq i.$$

When $||\cdot||$ is the Euclidean norm (possibly weighted), the quantizer cells R_*^i , $1 \leq i \leq m$, are convex polygons and form a *Voronoi partition* of $\mathbb{R}^n$, and furthermore q_*^i is the centroid of R_*^i with respect to the stationary distribution F_X of x_k , i.e., $q_*^i = E[x_k | x_k \in R_*^i]$. As a consequence, the optimal quantizer is statistically unbiased, i.e., $E[n_k] = 0$, and furthermore x_k^q and the quantizer noise n_k are uncorrelated at time k , i.e., $E[x_k n_k^T] = 0$. However, note that n_k and x_k^q may be correlated for $j \neq k$, and (n_k) may itself be a correlated process.

If M is large (i.e., the quantizer is *high resolution* or *fine*), then each region R_i will typically be very small, so that f_X will not vary much on each R^i . This yields a conditional pdf of x_k given R_i that is approximately uniform on R_i . For the case when X is scalar-valued and Q is a uniform, midpoint quantizer on an interval $[a, b]$, these considerations yield the asymptotic formula

$$D \approx (b - a)^2 / (12M^2), \quad (3)$$

provided that the overload regions – i.e., the tails of $f_X(x)$ on the regions $x < a$ or $x > b$ – make negligible contributions to D . Note that this expression does not depend on the distribution of the input.

For large M , it can also be shown that the optimal vector quantizer has a normalized point density (proportion of points per unit volume) proportional to $f_X^{1/3}$ and an optimal distortion

$$D_{\min} \approx \frac{c}{M^2} \left(\int f_X(x)^{1/3} d\mu(x) \right)^3, \quad (4)$$

where the constant c depends only on n .

Quantized Control: Basic Formulation

Much of the theory of quantized control concerns finite-dimensional linear time-invariant (LTI) plants. A formulation is provided in this section to help fix ideas, for the case of a single feedback loop containing a single errorless digital channel.

Consider the discrete-time plant

$$x_{k+1} = Ax_k + Bu_k + v_k, \quad y_k = Fx_k + w_k, \quad (5)$$

where at every time $k \in \mathbb{Z}_{\geq 0}$, $x_k \in \mathbb{R}^n$ is the state with x_0 unknown, $u_k \in \mathbb{R}^m$ is the control input, $y_k \in \mathbb{R}^p$ is the measured output, $v_k \in \mathbb{R}^n$ is unknown process noise, $w_k \in \mathbb{R}^p$ is unknown measurement noise, and A , B , and F are constant known matrices of appropriate dimensions. For the problem to be well posed, assume that the matrix pairs (A, B) and (F, A) are, respectively, reachable and observable. Suppose that the output sensors communicate with the controller over a digital channel that can carry one symbol s_k from a finite, possibly time-varying alphabet $\mathcal{S}_k$ of cardinality $M_k \geq 1$ during the $(k + 1)$ -th sampling interval. Assume for simplicity that the channel is errorless, with negligible propagation delay. The asymptotic average rate at which the channel transports data may then be defined as

$$R := \lim_{k \rightarrow \infty} \frac{1}{k} \sum_{j=0}^{k-1} \log_2 M_j \text{ (bits/sample)}. \quad (6)$$

Note that if the channel alphabet $\mathcal{S}_k$ is constant or varies periodically with k , the inferior limit reduces to a straight limit.

In full generality, each transmitted symbol may depend on all past and present measurements and past symbols,

$$s_k = \gamma_k(y_0^k, s_0^{k-1}) \in \mathcal{S}_k, \quad \forall k \in \mathbb{Z}_{\geq 0}, \quad (7)$$

where γ_k is the coder mapping at time k . At time k the controller has $s_0, \dots, s_k$ available and then applies a control law of the general form

$$u_k = \delta_k(s_0^k) \in \mathbb{R}^m, \quad \forall k \in \mathbb{Z}_{\geq 0}, \quad (8)$$

where δ_k is the controller mapping at time k .

In practice, additional memory or structural constraints are usually placed on the general coding and control rules (7) and (8). For instance, if a static quantizer of the form (1) is used, then the coding alphabet $\mathcal{S}_k \equiv \mathcal{S}$ will be constant, and $s_k \equiv \gamma(y_k)$ will represent the index of the quantizer cell that contains y_k . Similarly, a static, memoryless controller is captured by setting $u_k = \delta(s_k)$ in (8).

Finite-dimensional coding and control laws may be formulated by defining internal coder and controller states ψ_k^γ and ψ_k^δ with local updates of the form

$$s_k = \gamma(y_k, \psi_{k-1}^\gamma), \quad \psi_k^\gamma = \phi(s_k, \psi_{k-1}^\gamma), \quad (9)$$

$$\psi_k^\delta = \eta(s_k, \psi_{k-1}^\delta), \quad u_k = \delta(\psi_k^\delta). \quad (10)$$

If the states ψ_k^γ and ψ_k^δ are finite valued, then the coding and control laws are called *finite-state*.

Additive Noise Model

Early approaches to quantized control modeled quantization errors as additive uncorrelated noise, in order to allow the use of well-developed tools from linear stochastic control (Curry

1970). While this is reasonable at high quantizer resolution, it fails to capture two key properties.

A simple example illustrates this. Consider a scalar, noiseless, fully observed, unstable LTI plant – i.e., (5) with $n = 1$, $A = a$ with $|a| > 1$, $B, C = 1$, and $w_k, v_k = 0$ – where x_0 is a random variable. Under static, high-resolution uniform quantization, the data available to the controller is expressed as a noisy linear measurement

$$y'_k := Q(x_k) = x_k + n_k, \quad k \in \mathbb{Z}_{\geq 0},$$

where the quantizer error process (n_k) is treated as zero mean white noise uncorrelated with (x_k) and having constant variance given by (3).

The first shortcoming of the additive noise approach is that it precludes the possibility of asymptotic mean-square stability, which would effectively require the controller to estimate the initial state x_0 with a mean-square error diminishing strictly faster than a^{-2k} . This turns out to be impossible under the uncorrelatedness assumption and the constraint $|a| > 1$.

However, in the seminal paper (Delchamps 1990), it was shown that asymptotic stability could in fact be achieved, by using a nonlinear controller that exploited the correlation between successive quantizer errors. To see this, suppose that the unknown initial state x_0 is confined to a known interval $[-l_0, l_0]$. At time $k \geq 0$, suppose that $l_k \geq 0$, $k = 1, 2, \dots$ represent bounds to be determined on the future states x_k . Let Q be a static one-bit quantizer – i.e., with $M = 2$ – such that $Q(x) = 1$ if $x \geq 0$ and $Q(x) = -1$ if $x < 0$. At time k let $u_k = -0.5al_k Q(x)$ so that

$$x_{k+1} = \begin{cases} a(x_k - 0.5l_k) & \text{if } 0 \leq x_k \leq l_k \\ a(x_k + 0.5l_k) & \text{if } -l_k \leq x_k < 0 \end{cases}.$$

$$\Rightarrow |x_{k+1}| \leq 0.5|a|l_k =: l_{k+1}.$$

If $|a| < 2$ then $l_k \rightarrow 0$, and asymptotic stability is achieved uniformly and with exponential convergence.

The second, and main, drawback of the additive white noise model is that it does not predict the loss of closed-loop stability when the quantizer resolution is too coarse. This is because the number M of quantizer points only serves

to determine the variance of the additive noise n_k : reducing M increases the variance of n_k and the mean-square states, but they remain bounded over time. In contrast, a rigorous analysis reveals that stability is impossible by any means, linear or nonlinear, when M drops below a certain threshold.

Numerous proofs of this loss of stability exist. In a stochastic setting, the argument is based on fixing the coder and controller and expanding out the closed-loop dynamics of the scalar LTI plant to write

$$x_k = a^k x_0 - a^k z_k \quad (11)$$

where $z_k := -a^{-k} \sum_{j=0}^{k-1} a^{k-j-1} u_j$. As z_k is a function of $s_0^{k-1} \in \mathcal{S}^k$, it can take at most M^k values. Furthermore, in the absence of noise, it is fully determined by x_0 , for a given coding and control policy (7) and (8). Thus z_k can be regarded as the output $Q'_k(x_0)$ of an M^k -valued quantizer. Substituting this into (11) yields

$$x_k = a^k (x_0 - Q'_k(x_0)).$$

From the asymptotic quantizer result (4), it then follows that for large k ,

$$\mathbb{E}[x_k^2] \geq c \frac{a^{2k}}{M^{2k}} \left(\int f_{X_0}(x)^{1/3} d\mu(x) \right)^3.$$

Thus a necessary condition for asymptotic mean-square stabilizability is that $M > |a|$ – see Nair and Evans (2000) for details.

The Data Rate Theorem

The discussions above emphasized the need for a more rigorous approach to quantized control. In the literature, the necessary condition $M > |a|$ was first derived in a nonrandom setting, where it was shown to be both sufficient and necessary to be able to ensure uniform stability (Wong and Brockett 1999; Baillieul 1999).

The sufficiency argument is constructive. Let Q be an M -level uniform quantizer on $[-1, 1]$, with cells formed by partitioning $[-1, 1]$ into M subintervals $R^1, \dots, R^M$ of equal length and

setting $Q(z)$ to be the midpoint of R^i when $z \in R^i$. Suppose that at time k , the unknown state x_k lies in a known interval $[-l, l]$, and set $u_k = -alQ(x_k/l)$. Thus

$$\begin{aligned} |x_{k+1}| &= |a||x_k - lQ(x_k/l)| \\ &= |a|l \left| \frac{x}{l} - Q\left(\frac{x}{l}\right) \right| \leq |a| \frac{l}{M}. \end{aligned}$$

When $M > |a|$, the right-hand side $< l$. Thus $x_{k+1} \in [-l, l]$ as well, and boundedness is achieved. Uniform asymptotic stability can be achieved by replacing the constant parameter l in the argument above with a time-varying bound l_k , updated as $l_{k+1} = |a|l_k/M \rightarrow 0$.

The necessity argument is based on volume partitioning. The basic idea is to fix an arbitrary coding and control policy and let m_k be the Lebesgue measure of the set of values that x_k can take at time $k \in \mathbb{Z}_{\geq 0}$. After k time steps, the plant dynamics expand this uncertainty volume m_0 by a factor $|a|^k$. However, the coder effectively divides this region into M^k disjoint, exhaustive pieces, each of which is shifted by the controller. As Lebesgue measure is translation invariant, it then follows that $m_k \geq |a|^k m_0 / M^k$. Consequently M must exceed $|a|$ if the closed loop is uniformly asymptotically stable.

The tight criterion $M > |a|$, or equivalently $R > \log_2 |a|$, was the first instance of the *data rate theorem*. Volume-partitioning arguments and Jordan canonical forms can be used to generalize it to LTI plants with vector-valued states, yielding the necessary and sufficient condition

$$R > \sum_{i: |\lambda_i| \geq 1} \log_2 |\lambda_i| =: H, \quad (12)$$

Where $\lambda_1, \dots, \lambda_n$ are the eigenvalues of A . This criterion is remarkably universal, having been shown to be tight for a variety of settings and objectives: e.g., for asymptotic r -th moment stabilizability with random, unbounded x_0 and no process or measurement noise (Nair and Evans 2003); uniform stabilizability with bounded x_0 and no process or measurement noise (Baillieul 2002); and uniform stabilizability with bounded initial state, process, and measurement noise

(Hespanha et al. 2002; Tatikonda and Mitter 2004).

When the plant noise is random and unbounded, mean-square stability can be achieved using a time-varying bit rate with average value arbitrarily close to but strictly exceeding H (Nair and Evans 2004). If in addition the bit rate is constrained to be constant, an interesting subtlety arises, and the minimum rate is given by $R_{\min} = \log_2 \left[1 + \prod_{i: |\lambda_i| \geq 1} |\lambda_i| \right]$ (Kostina et al. 2018).

The deep nature of (12) becomes even clearer when it is noted that the right-hand side of (12) coincides with the intrinsic entropy generation rate H of the (open-loop) plant, in both the Kolmogorov-Sinai and topological senses; that is, it describes the growth rate of the number of “distinguishable” state trajectories. Thus the data rate theorem states that stability is possible if the communication rate in the feedback loop exceeds the rate at which the plant generates uncertainty. This interpretation leads to the notion of *feedback entropy* (see cross-reference to article by C. Kawan).

Zooming Quantized Control

When the plant noise and initial state of the plant (5) are bounded, stability (in a uniform sense) can be guaranteed by applying a linear observer to track the plant states with bounded error and then applying a suitable static, memoryless coding and control policy on the observer states x_k^o .

However, if the noise or initial state has unbounded support – e.g., when they are Gaussian or when prior bounds on them are not known – then stability cannot be achieved by any such static memoryless scheme or indeed by any scheme where the control inputs (8) are bounded (Nair and Evans 2004). The explanation is simple: due to the infinite support, there is a nonzero probability that the propagated state Ax_t will be beyond reach of the control input at some time t . The unstable plant dynamics then amplify this shortfall, causing the same phenomenon to

occur with increasing probability at subsequent times and inevitably leading to instability.

One solution is to use a *zooming quantizer*, i.e., having a dynamic range $l_k > 0$ that is not bounded a priori but expands or contracts according to the most recent symbol (Brockett and Liberzon 2000). In the noiseless case, if this symbol corresponds to the “overload region” of the quantizer (as indicated by a special symbol), then the range is updated as $l_{k+1} := \phi_{\text{out}} l_k$, where $\phi_{\text{out}} > 1$ is the “zoom-out” factor. Otherwise $l_{k+1} := \phi_{\text{in}} l_k$, where $\phi_{\text{in}} < 1$ is the “zoom-in” coefficient.

In the communications literature, such schemes are called *adaptive quantizers* (Goodman and Gersho 1974). If ϕ_{out} is sufficiently large compared to the unstable open-loop eigenvalues, and if ϕ_{in} is not too small, then global asymptotic stability ensues. With unbounded noise in the plant, variants of this scheme guarantee mean-square stability at any data rate satisfying (12) (Nair and Evans 2004); other forms of stochastic stability (Yüksel 2010); or *input-to-state stability* (Liberzon and Nesic 2007).

Zooming quantization is an important example of a finite-dimensional coder-controller (9) and (10), with l_k playing the role of an internal state variable. As the range update is driven by the symbols, both coder and controller can each generate identical copies of l_k , provided that there are no errors in the channel and they both start from the same initial range l_0 .

Erroneous Digital Channels

The information-theoretic aspects of quantized control become especially pronounced when the channel is not error-free. In this case, the data rate theorem (12) can be extended, but in ways that are highly dependent on the precise setting and stability objective.

A common figure of merit for a stochastic discrete memoryless channel (DMC) is its *ordinary capacity* C . This is defined operationally as the largest block-code bit rate that can be transmitted across the channel with negligible probability of decoding error and also coincides with the largest

rate of Shannon information across the channel (Shannon 1948).

For a noiseless LTI plant with random initial state controlled over a DMC, the condition $C > H$ is a tight criterion for almost sure (a.s.) asymptotic stabilizability (Matveev and Savkin 2007a). This is a natural generalization of (12).

On the other hand, if the objective is to bound the state moments of a scalar LTI plant subject to bounded process noise, then the achievability of this goal is determined by the *anytime capacity* C_{any} (Sahai and Mitter 2006): this is essentially given by the fastest decay rate of the decoding error probability.

However, if the aim is a.s. boundedness of an LTI plant with random initial state and bounded, nonstochastic process noise, then the stabilizability criterion changes again to $C_{0f} > H$ (Matveev and Savkin 2007b). Here C_{0f} is the *zero-error feedback capacity* of the channel, defined as the largest block-code bit rate that can be transmitted across the channel with *exactly zero* probability of decoding error and with perfect channel feedback (Shannon 1956).

As $C_{0f} < C_{\text{any}} < C$ for most channels, these conditions do not coincide. This suggests that there is no universal, operationally relevant information theory for feedback control over error-prone channels: such a theory must instead be tailored to match the underlying objectives and assumptions. For systems with nonstochastic disturbances, preliminary steps in this direction have been taken in Nair (2015, 2013). The reader is also referred to You and Xie (2011) and Minero et al. (2013) for information-theoretic analyses of stochastic linear systems controlled via Markov channels.

Summary and Future Directions

This entry described the key elements of quantized control with finite data rates, emphasizing the interplay between coding and control. A great deal is now known about the fundamental limitations on stability in quantized control systems consisting a single feedback loop. Two major directions for future research suggest themselves:

- Little work has been done on designing optimal coding and control schemes or determining optimal performance at a given rate, apart from one or two special cases and structural results – see Nair et al. (2006, 2007) and the references therein. Lower and upper bounds on optimal performance have recently been derived in Kostina and Hassibi (2019). It is very unlikely that exact, closed-form solutions will be possible. However, numerical approaches based on the Lloyd-Max algorithm, particle filtering, and model-predictive control may prove fruitful.
- Networked control systems usually consist of a number of subsystems interconnected over a network. Furthermore, in multi-agent systems, the main objective may not be stability, but rather coordination or consensus to a common state. Comparatively little is known about the data rate requirements and information-theoretic aspects of these problems.

Quantum Networks

Matthew R. James

Research School of Electrical, Energy and Materials Engineering, Australian National University, Canberra, Australia

Abstract

In this entry we discuss a symbolic tool for describing the interconnection of open quantum systems using boson fields. The tool called the series product is expressed in terms of physical parameters. Boson fields, such as free quantum optical fields, serve as “wires” connecting components. The framework is general and allows for the description of networks consisting of quantum and classical components in a consistent and unified manner.

Quantum · Networks · Feedback · Control

Introduction

The purpose of this entry is to present some easy-to-use tools for constructing feedback networks involving quantum components and optical “wires.” What is presented in this entry is a simplification of a more general quantum feedback network theory (Yanagisawa and Kimura 2003; Gough and James 2009), which builds on earlier cascade theory (Gardiner 1993; Carmichael 1993), network quantization (Yurke and Denker 1984), and quantum control (Wiseman and Milburn 1994).

The basic idea is simple, Fig. 1. Take an output channel and connect it to an input channel. Such series or cascade connections are commonplace in classical electrical circuit theory. For instance, if the systems are resistors with resistances R_1 and R_2 , then the total series-connected system is equivalent to a single resistor with resistance $R = R_1 + R_2$. This use of simple parameters for devices, and rules for interconnecting devices in terms of these parameters, is a powerful feature of classical electrical circuit theory.

Specifically, what we wish to do is to take open quantum models G_1, G_2 for the two systems and combine them to form an equivalent open quantum model $G = G_2 \triangleleft G_1$, as in Fig. 2.

Open Quantum Systems

An atom interacting with an electromagnetic field is a fundamental example of an open quantum system, Fig. 3. Such systems were studied by Einstein which he described using his famous rate equations (Einstein 1916) for absorption and emission of photons. An atom in its ground state may absorb a quanta of energy from the field, while an excited atom may release quantized energy into the field. Modern models for open quantum systems (Gardiner and Zoller 2000) have an input-output structure, where the field is represented in terms of incoming and outgoing components.

In the absence of any other influences, the behavior of the atom will evolve in time according to the laws of quantum mechanics, as determined by the self-energy of the atom, the nature of the fields, and how they are coupled to the atom. The field channels may be used to gather information about the atom via photodetection and to influence the behavior of the atom by directing light onto the atom. The fields may also be used for interconnection, where, for example, the emitted light from one system could be directed onto another.

In quantum mechanics, systems can be represented in terms of an underlying Hilbert space. States are unit vectors in this space, and physical quantities are represented as operators; see, for example, Nielsen and Chuang (2000, Chapter 2). Together, states and operators provide a quantum noncommutative probabilistic model, Bouten et al (2007, Section 2.2). Measurements are described in these probabilistic terms, and dynamical evolution of states and operators is unitary – Schrodinger’s equation.

A simple two-level model for an atom may be described using the Pauli matrices

$$\begin{aligned}\sigma_0 = I &= \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad \sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \\ \sigma_y &= \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.\end{aligned}\quad (1)$$

Any physical quantity of the atom can be expressed in terms of these matrices. In particular, the atomic energy levels are the eigenvalues $\pm \frac{1}{2}\omega$ of the Hamiltonian $H = \frac{1}{2}\omega\sigma_z$ describing the self-energy of the atom.

The atom interacts with the field channels by an exchange of energy that may be described by first principles in terms of an interaction Hamiltonian, Gardiner and Zoller (2000, Chapter 3). In this entry we use an idealized quantum noise model for the open atom-field system which is well justified theoretically and experimentally, Hudson and Parthasarathy (1984), Gardiner and Collett (1985), Parthasarathy (1992), and Gardiner and Zoller (2000). The input field, $B(t)$, drives an interaction-picture equation for

a unitary operator $U(t)$ governing the atom-field system. If $|\psi_a\rangle$ and $|\psi_f\rangle$ are initial atomic and field states, respectively, the state of the atom-field system at time t is $U(t)|\psi_a\psi_f\rangle$. Here, we are using the standard Dirac “ket” notation for state vectors, with the tensor product notation $|\psi_a\psi_f\rangle = |\psi_a\rangle \otimes |\psi_f\rangle$.

Let’s now look at the equations governing the driven atomic system. We suppose that the field is initially in the vacuum state, which we denote by $|\psi_f\rangle = |0\rangle$. In this case the input process $B(t)$ is a quantum Wiener process, for which the non-zero Ito product is $dB(t)dB^\dagger(t) = dt$. The atom-field coupling is determined by coupling operator $L = \sqrt{\kappa}\sigma_-$, where

$$\sigma_- = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}$$

is the lowering operator (the raising operator is defined by $\sigma_+ = \sigma_-^\dagger$) and $\kappa > 0$ describes the strength of the coupling to the field. The evolution of the unitary $U(t)$ is given by the Schrodinger equation

$$dU(t) = \left\{ dB^\dagger(t)L - L^\dagger dB(t) - \frac{1}{2}(L^\dagger L + iH)dt \right\} U(t), \quad (2)$$

where $L = \sqrt{\kappa}\sigma_-$ and $H = \frac{1}{2}\omega\sigma_z$. Equation (2) is *quantum stochastic differential equation*, expressed in quantum-Ito differential form.

In the Heisenberg picture, atomic operators X evolve according to $X(t) = U^\dagger(t)XU(t)$, so that we have

$$\begin{aligned}dX(t) &= (-i[X(t), H(t)] + \mathcal{L}_{L(t)}(X(t)))dt \\ &\quad + dB^\dagger(t)[X(t), L(t)] \\ &\quad + [L^\dagger(t), X(t)]dB(t),\end{aligned}\quad (3)$$

and

$$\mathcal{L}_L(X) = \frac{1}{2}L^\dagger[X, L] + \frac{1}{2}[L^\dagger, X]L. \quad (4)$$

The output field is defined by $B_{\text{out}}(t) = U^\dagger(t)B(t)U(t)$, which in differential form is

given by the equation

$$dB_{\text{out}}(t) = L(t)dt + dB(t). \quad (5)$$

Explicitly, for the operators $X = \sigma_x$, σ_y , and σ_z , we have, with $L = \sqrt{\kappa} \sigma_-$ and $H = \frac{1}{2}\omega\sigma_z$,

$$\begin{aligned} d\sigma_x(t) = & (-\omega\sigma_y(t) - \frac{\kappa}{2}\sigma_x(t))dt \\ & + \sqrt{\kappa}(dB^\dagger(t)\sigma_z(t) + \sigma_z(t)dB(t)) \end{aligned} \quad (6)$$

$$\begin{aligned} d\sigma_y(t) = & (\omega\sigma_x(t) - \frac{\kappa}{2}\sigma_y(t))dt \\ & - i\sqrt{\kappa}(\sigma_z(t)dB^\dagger(t) - \sigma_z(t)dB(t)) \end{aligned} \quad (7)$$

$$\begin{aligned} d\sigma_z(t) = & (-\kappa\sigma_z(t) - \kappa)dt \\ & - 2\sqrt{\kappa}(dB^\dagger(t)\sigma_-(t) + \sigma_+(t)dB(t)), \end{aligned} \quad (8)$$

with output equation

$$dB_{\text{out}}(t) = \sqrt{\kappa} \sigma_-(t)dt + dB(t). \quad (9)$$

The equations of motion for the atomic state density operator ρ (convex combinations of outer products $|\psi\rangle\langle\psi|$) may be obtained by averaging out the noise in the Schrodinger picture, $\rho(t) = \text{tr}_B[U(t)(\rho \otimes |0\rangle\langle 0|)U^\dagger(t)]$; here, we take the field to be in the vacuum state. The differential equation for $\rho(t)$ is

$$\dot{\rho}(t) = i[\rho(t), H] + \mathcal{L}_L^\dagger(\rho(t)) \quad (10)$$

where

$$\mathcal{L}_L^\dagger(\rho) = \frac{1}{2}[L, \rho L^\dagger] + \frac{1}{2}[L\rho, L^\dagger]. \quad (11)$$

Equation (10) is called the *master equation*, and $i[\rho, H] + \mathcal{L}_L^\dagger(\rho)$ is called the *Lindblad super-operator* (in Schrodinger form). The equations of motion for the averages $x(t) = \text{tr}[\rho(t)\sigma_x]$, $y(t) = \text{tr}[\rho(t)\sigma_y]$, and $z(t) = \text{tr}[\rho(t)\sigma_z]$ are

$$\dot{x}(t) = -\frac{\kappa}{2}x(t) - \omega y(t), \quad (12)$$

$$\dot{y}(t) = -\frac{\kappa}{2}y(t) + \omega x(t), \quad (13)$$

$$\dot{z}(t) = -\kappa z(t) - \kappa, \quad (14)$$

In Equations (12), (13), and (14), we can see the effect of the field coupling, which causes $x(t) \rightarrow 0$, $y(t) \rightarrow 0$, and $z(t) \rightarrow -1$ as $t \rightarrow \infty$, i.e., $\rho(t) \rightarrow \frac{1}{2}(\sigma_z - I) = |-1\rangle\langle -1|$, the pure state of lowest energy.

Notice that once the physical parameters H and L and initial states are given, the equations of motion can readily be derived.

Series Network

Let's see how we can achieve a simple, symbolic rule involving the physical parameters $G = (L, H)$ analogous to $R = R_1 + R_2$ for the series connection of two open quantum systems, where the input and output channels are quantum fields. As mentioned in the example of the atom above, the physical parameters determining open quantum systems are a Hamiltonian H describing the self-energy of the system and a vector L of operators describing how the system is coupled to the field channels. Actually, there is a third parameter S , a self-adjoint matrix of operators describing scattering between field channels, that was introduced in Hudson and Parthasarathy (1984) and Parthasarathy (1992). While S does not appear in the Lindblad nor the master equation for a single system, it does have nontrivial use in several applications including quantum feedback networks (such as those including beamsplitters). Thus in general an open quantum system, call it G , is characterized by three parameters $G = (S, L, H)$. However, in this entry we do not use the scattering parameter, and so we set $S = I$; actually, we make the abbreviation $G = (L, H)$.

For example, the parameters for the atom, coupled to two field channels, call it A , are

$$A = \left(\begin{pmatrix} \sqrt{\kappa_1} \sigma_- \\ \sqrt{\kappa_2} \sigma_- \end{pmatrix}, \frac{1}{2}\omega\sigma_z \right). \quad (15)$$

Here,

$$L = \begin{bmatrix} L_1 \\ L_2 \end{bmatrix}, \quad (16)$$

where $L_1 = \sqrt{\kappa_1} \sigma_-$, $L_2 = \sqrt{\kappa_2} \sigma_-$, and $H = \frac{1}{2} \omega \sigma_z$.

In network modeling, and indeed in modeling in general, it can be helpful to decompose large systems into smaller pieces and to assemble large systems from components. In Gough and James (2009), the *concatenation product* $\boxplus$ was introduced to assist with this. The concatenation product is defined by

$$(L_1, H_1) \boxplus (L_2, H_2) = \left(\begin{pmatrix} L_1 \\ L_2 \end{pmatrix}, H_1 + H_2 \right). \quad (17)$$

For the atom, if we wish to decompose it with respect to field channels, we may write

$$A = (\sqrt{\kappa_1} \sigma_-, \frac{1}{2} \omega \sigma_z) \boxplus (\sqrt{\kappa_2} \sigma_-, 0). \quad (18)$$

Now suppose we have two systems $G_1 = (L_1, H_1)$ and $G_2 = (L_2, H_2)$, as in Fig. 1. Because the systems are separated spatially, the field segment connecting the output of G_1 to the input of G_2 has non-zero length, and so this means there is a small delay τ in the transmission of quantum information from G_1 to G_2 . That is, $B_{\text{in},2}(t) = B_{\text{out},1}(t - \tau)$. Now if the systems are sufficiently close, τ will be small compared with the timescales of the systems and may be neglected. In this zero-delay limit, the output of the second system is given by, using the output equations,

$$\begin{aligned} dB_{2,\text{out}}(t) &= L_2(t)dt + (L_1(t)dt + dB_1(t)), \\ &= (L_1(t) + L_2(t))dt + dB_1(t). \end{aligned} \quad (19)$$

(20)

This suggests an effective coupling $L = L_1 + L_2$.

In this way, a Markovian model for the series connection $G = G_2 \triangleleft G_1$ may be derived. In terms of the physical parameters, the *series product* (defined in Gough and James 2009) is given by

$$\begin{aligned} (L_2, H_2) \triangleleft (L_1, H_1) \\ = (L_1 + L_2, H_1 + H_2 + \text{Im}[L_2^\dagger L_1]). \end{aligned} \quad (21)$$

Thus the series connection $G_{\text{series}} = G_2 \triangleleft G_1$ has parameters $L = L_1 + L_2$ and $H = H_1 + H_2 + \text{Im}[L_2^\dagger L_1]$, analogous to the expression $R = R_1 + R_2$ for series-connected resistors.

Coherent Feedback

The series product serves very well for Markovian approximations to cascades of independent open systems. However, importantly for us, the series product may also be used to describe an important class of *quantum feedback networks*. This is because the two systems $G_1 = (L_1, H_1)$ and $G_2 = (L_2, H_2)$ need not be independent – they can be parts of the same system.

For example, suppose we take G_1 to be the first factor in the decomposition (18) of A , i.e., $G_1 = (\sqrt{\kappa_1} \sigma_-, \frac{1}{2} \omega \sigma_z)$, and $G_2 = (\sqrt{\kappa_2} \sigma_-, 0)$ the second. Before feedback, the Heisenberg evolution equations for the system $A = (\sqrt{\kappa_1} \sigma_-, \frac{1}{2} \omega \sigma_z) \boxplus (\sqrt{\kappa_2} \sigma_-, 0)$ are

$$\begin{aligned} d\sigma_x(t) &= (-\omega \sigma_y(t) - \frac{\kappa_1 + \kappa_2}{2} \sigma_x(t))dt \\ &\quad + \sqrt{\kappa_1} (dB_1^\dagger(t) \sigma_z(t) + \sigma_z(t) dB_1(t)) \\ &\quad + \sqrt{\kappa_2} (dB_2^\dagger(t) \sigma_z(t) + \sigma_z(t) dB_2(t)) \end{aligned} \quad (22)$$

$$\begin{aligned} d\sigma_y(t) &= (\omega \sigma_x(t) - \frac{\kappa_1 + \kappa_2}{2} \sigma_y(t))dt \\ &\quad - i\sqrt{\kappa_1} (dB_1^\dagger(t) \sigma_z(t) - \sigma_z(t) dB_1(t)) \\ &\quad - i\sqrt{\kappa_2} (dB_2^\dagger(t) \sigma_z(t) - \sigma_z(t) dB_2(t)) \end{aligned} \quad (23)$$

$$\begin{aligned} d\sigma_z(t) &= (-\kappa_1 - \kappa_2)(\sigma_z(t) + 1)dt \\ &\quad - 2\sqrt{\kappa_1} (dB_1^\dagger(t) \sigma_-(t) + \sigma_+(t) dB_1(t)) \\ &\quad - 2\sqrt{\kappa_2} (dB_2^\dagger(t) \sigma_-(t) + \sigma_+(t) dB_2(t)) \end{aligned} \quad (24)$$

with output equations

$$dB_{1,\text{out}}(t) = \sqrt{\kappa_1} \sigma_-(t)dt + dB_1(t), \quad (25)$$

$$dB_{2,\text{out}}(t) = \sqrt{\kappa_2} \sigma_-(t)dt + dB_2(t). \quad (26)$$

The series connection for the fields gives

$$\begin{aligned} dB_2(t) &= dB_{1,\text{out}}(t) \\ &= \sqrt{\kappa_1} \sigma_-(t)dt + dB_1(t). \end{aligned} \quad (27)$$

One may now be tempted to substitute equation (27) into equations (22), (23), and (24). However, one must be careful because the Ito increments commute with system operators, e.g., $dB_2^\dagger(t)\sigma_z(t) = \sigma_z(t)dB_2^\dagger(t)$, whereas $\sigma_z\sigma_- \neq \sigma_-\sigma_z$. Fortunately, the substitutions are correct provided we preserve the normal ordering given in (22), (23), and (24), Gough and James (2017). An expression is normally ordered if the adjoints all appear on the left, e.g., $A^\dagger B + B^\dagger A$. For instance, performing the normally ordered substitutions in equation (22) gives

$$\begin{aligned} d\sigma_x(t) &= (-\omega\sigma_y(t) - \frac{\kappa_1 + \kappa_2}{2}\sigma_x(t))dt \\ &\quad + \sqrt{\kappa_1}(dB_1^\dagger(t)\sigma_z(t) + \sigma_z(t)dB_1(t)) \\ &\quad + \sqrt{\kappa_2}((\sqrt{\kappa_1}\sigma_+(t)dt + dB_1^\dagger(t))\sigma_z(t) \\ &\quad + \sigma_z(t)(\sqrt{\kappa_1}\sigma_-(t)dt + dB_1(t))) \end{aligned} \quad (28)$$

Quantum Networks,

Fig. 4 Atom in a measurement feedback loop with a classical controller

$$\begin{aligned} &= (-\omega\sigma_y(t) - \frac{(\sqrt{\kappa_1} + \sqrt{\kappa_2})^2}{2}\sigma_x(t))dt \\ &\quad + (\sqrt{\kappa_1} + \sqrt{\kappa_2})(dB_1^\dagger(t)\sigma_z(t) \\ &\quad + \sigma_z(t)dB_1(t)) \end{aligned} \quad (29)$$

This corresponds to the series connection

$$\begin{aligned} G_{fb} &= (\sqrt{\kappa_2}\sigma_-, 0) \triangleleft \left(\sqrt{\kappa_1}\sigma_-, \frac{1}{2}\omega\sigma_z \right) \\ &= \left((\sqrt{\kappa_1} + \sqrt{\kappa_2})\sigma_-, \frac{1}{2}\omega\sigma_z \right) \end{aligned} \quad (30)$$

which describes the coherent feedback arrangement shown in Fig. 2. The system G_{fb} is an open quantum system with Hamiltonian $H = \frac{1}{2}\omega\sigma_z$ that is coupled to a single field channel via the coupling operator $L = (\sqrt{\kappa_1} + \sqrt{\kappa_2})\sigma_-$.

Measurement Feedback

In general quantum feedback networks may include both quantum and classical components. For instance, in a measurement feedback system, the controller is a classical dynamical system that processes a signal made from measurements of the quantum system, and these measurement results are processed to determine control actions. An example is shown in Fig. 4. Here, an output channel of the atom discussed above is continuously monitored by homodyne detection

(HD). The classical measurement signal $Y(t)$ is fed as an input into a classical controller. The classical controller might, for example, be constructed from ordinary analog or digital electronics. The control signal $u(t)$ produced is used to modulate an input channel of the atom. In this way, a quantum-classical closed-loop system is formed.

Ideal homodyne detection of the first channel of the atom may be described by

$$Y(t) = B_{\text{out},1}(t) + B_{\text{out},1}^\dagger(t). \quad (31)$$

Here, the signal is self-adjoint and commutative $[Y(t), Y(s)] = 0$ and so by the spectral theorem (Bouten et al 2007, Theorem 2.4) is equivalent to a classical stochastic process. The classical control signal $u(t)$ modulates a vacuum field $B_3(t)$ to produce the atom's second input $B_2(t) = B_{\text{out},3}(t)$:

$$dB_{\text{out},3}(t) = u(t)dt + dB_3(t). \quad (32)$$

Both homodyne detection and modulation are standard procedures in quantum optics (Bachor and Ralph 2004).

We suppose (for simplicity) that the controller is a first-order linear system

$$dx(t) = -ax(t)dt + bdY(t) \quad (33)$$

$$u(t) = cx(t). \quad (34)$$

Equations (31), (32), (33), and (34) involve a mixture of quantum and classical variables. We may regard the classical variables as belonging to a commutative subsystem of a larger, composite noncommutative quantum system. One way to describe this is to represent the controller dynamics in terms of an open quantum $C = C_1 \boxplus C_2$, where

$$C_1 = (cq, -\frac{\alpha}{2}(qp + pq)) \quad (35)$$

and

$$C_2 = (-ibp, 0). \quad (36)$$

Here, q and p are the canonical position and momentum operators defined by $q\varphi(x) = x\varphi(x)$, $p\varphi(x) = -i\frac{d}{dx}\varphi(x)$, and the underlying Hilbert space for C is $\mathfrak{H}_C = L^2(\mathbf{R})$. The open quantum system C has inputs $B_3(t)$ and $B_4(t)$.

For $X = \varphi$ a smooth function, we have from (3)

$$d\varphi = (-a\varphi' + \frac{1}{2}b^2\varphi'')dt + b\varphi'd(B_4(t) + B_4^\dagger(t)), \quad (37)$$

and in particular when $\varphi(q) = q$ and $B_4(t) = B_{\text{out},1}(t)$, this reduces to

$$dq = -aqdt + bdY(t), \quad (38)$$

which represents the classical dynamics (33).

From the general expression (5), the first output of the system C is given by

$$dB_{\text{out},3}(t) = cq(t)dt + dB_3(t) \quad (39)$$

This corresponds to the modulator output (32) (Fig. 5).

Now that the classical and quantum components are represented at the same level, we may

Quantum Networks, Fig. 5 Quantum representation of an atom in a measurement feedback loop with a classical controller

apply the series product to determine the parameters of the measurement feedback system. From the above representations, the parameters for the measurement feedback system are

$$\begin{aligned}
 G_{mfb} &= (C_2 \triangleleft G_1) \boxplus (G_2 \triangleleft C_1) \\
 &= \left(-ibp + \sqrt{\kappa_1} \sigma_-, \frac{1}{2} \omega \sigma_z \right. \\
 &\quad \left. + \frac{1}{2} \sqrt{\kappa_1} bp \sigma_x \right) \\
 &\boxplus \left(\sqrt{\kappa_2} \sigma_- + cq, -\frac{\alpha}{2} (qp + pq) \right. \\
 &\quad \left. + \frac{1}{2} \sqrt{\kappa_2} cq \sigma_y \right). \quad (41)
 \end{aligned}$$

Summary and Future Directions

We have seen that idealized models for open quantum systems provide a powerful framework for describing feedback networks that include quantum as well as classical systems. This framework is based on quantum stochastic calculus, part of a general noncommutative quantum probability theory. The systematic exploitation of the concepts and methods from noncommutative quantum probability theory is seen as important for the future development of quantum technology, as it emerges from basic physics.

The series product is a fundamental symbolic tool for representing series connections of open quantum systems. The series product provides a recipe for determining the physical parameters of systems connected in series. Once the parameters are known, dynamical equations for the network can be easily derived. The derivation of the dynamical network equations using the series product is equivalent to algebraic substitutions in equations provided the normally ordered form is preserved. The series product is symbolic in nature, and indeed symbolic tools, such as the *Quantum Hardware Description Language (QHDL)*, are beginning to emerge, Tezak et al (2012).

Quantum Stochastic Processes and the Modelling of Quantum Noise

Hendra I. Nurdin

School of Electrical Engineering and Telecommunications, University of New South Wales (UNSW), Sydney, NSW, Australia

Abstract

This brief entry gives an overview of quantum mechanics as a *quantum probability theory*. It begins with a review of the basic operator-algebraic elements that connect probability theory with quantum probability theory. Then quantum stochastic processes are formulated as a generalization of stochastic processes within the framework of quantum probability theory. Quantum Markov models from quantum optics are used to explicitly illustrate the underlying abstract concepts and their connections to the quantum regression theorem from quantum optics.

Keywords

Quantum feedback control · Quantum stochastic systems · Quantum stochastic control

Introduction

Many phenomena display dynamics that appear to be random and can often be accurately modeled as stochastic processes. The modern theory of stochastic processes is built upon the measure-theoretic axiomatization of probability theory as developed by Kolmogorov in the 1930s; for a historical overview, see, e.g., Bingham (2000); Shafer and Vovk (2006). These theories underpin the stochastic systems theory and stochastic control theory that find wide applications in disciplines such as engineering (in particular control engineering), economics, and mathematical finance. At the atomic size

and energy scales, where classical physics is superseded by quantum mechanics, randomness is inherent. Indeed, measurement of a quantum mechanical system yields a random outcome, as dictated by the measurement postulate of quantum mechanics. Research into the axiomatic foundation of quantum mechanics since the seminal work of von Neumann have led to the recognition that quantum mechanics is essentially a noncommutative generalization of probability theory. That is, *quantum mechanics is a quantum probability theory*.

Quantum probability theory provides a rigorous basis for studying quantum stochastic processes and developing a modern formulation of quantum stochastic systems and control theory. This facilitates the systematic formulation and solution of estimation and feedback control problems for quantum systems (Bouten et al. 2007; Bouten and van Handel 2008; Gough and James 2009b; Nurdin and Yamamoto 2017). This entry provides an overview of quantum probability theory and the formulation of quantum stochastic processes and quantum Markov processes based on this theory. The abstract mathematical concepts introduced will then be explicitly illustrated in the context of quantum Markov models for a large class of quantum optical devices.

We will use fairly standard notations, with additional notations introduced later in the text. $\mathbb{R}$, $\mathbb{C}$, and $\mathbb{R}_{0+}$ denote the real and complex numbers and $\mathbb{R}_{0+} = [0, \infty)$, respectively. For $c \in \mathbb{C}$, $\bar{c}$ is its complex conjugate. For a complex-valued function X , $\bar{X}(\cdot) = \overline{X(\cdot)}$. For a set S , S^n denotes the n -fold direct product $S^n = \underbrace{S \times S \times \cdots \times S}_{n \text{ times}}$.

The indicator function for a set A is denoted by $\mathbf{1}_A$. A Dirac ket $|x\rangle$ denotes a complex vector in a Hilbert space, while a bra $\langle x|$ denotes the conjugate transpose (or dual functional) of the vector. Thus $\langle x|y\rangle$ is the inner product of $|x\rangle$ and $|y\rangle$. For any operator X mapping a Hilbert space to another, $X^\dagger$ denotes the adjoint of X (if X maps a Hilbert space to itself, then $X^\dagger$ is also referred to as the Hermitian conjugate). $\text{Tr}(X)$ denotes the trace of a trace-class operator. For a self-adjoint (Hermitian) operator, X , $X \geq 0$

denotes a positive operator, $\langle x|X|x \rangle \geq 0$ for all elements x of the Hilbert space.

Quantum Probability Theory and Quantum Stochastic Processes

A (classical) (In this entry we will use the qualifier “classical” in brackets to emphasize that a theory is not quantum mechanical.) probability space is a tuple $(\Omega, \mathcal{F}, \mathbb{P})$, where Ω is the sample space, $\mathcal{F}$ the event set as a σ -algebra of subsets of Ω , and $\mathbb{P}$ is a probability measure on the measure space $(\Omega, \mathcal{F})$. We endow $\mathbb{C}$ with its Borel σ -algebra $\mathcal{B}(\mathbb{C})$, making $(\mathbb{C}, \mathcal{B}(\mathbb{C}))$ a measurable space. A random variable $X : (\Omega, \mathcal{F}) \rightarrow (\mathbb{C}, \mathcal{B}(\mathbb{C}))$ is a measurable complex-valued map from Ω to $\mathbb{C}$ (for the sake of simplicity, we intentionally restrict ourselves only to random variables taking values in $\mathbb{C}$). The expectation value $\mathbb{E}[X]$ of X is given by $\mathbb{E}[X] = \int_{\Omega} X(\omega) P(d\omega)$. Given a sub- σ -algebra $\mathcal{G}$ of $\mathcal{F}$, the conditional expectation of a random variable X on $\mathcal{G}$, denoted by $\mathbb{E}[X|\mathcal{G}]$, is a random variable with the properties (i) $\mathbb{E}[X|\mathcal{G}]$ is $\mathcal{G}$ -measurable and (ii) $\mathbb{E}[\mathbb{E}[X|\mathcal{G}]K] = \mathbb{E}[XK]$ for any $\mathcal{G}$ -measurable random variable K . It follows from this definition that if $\mathcal{G}$ and $\mathcal{H}$ are sub- σ -algebras of $\mathcal{F}$ with $\mathcal{H} \subset \mathcal{G}$, then $\mathbb{E}[\mathbb{E}[X|\mathcal{G}]|\mathcal{H}] = \mathbb{E}[X|\mathcal{H}]$ (the tower property).

For the rest of the entry, let $T \subseteq \mathbb{R}$ denote a time index. For example, T can be discrete as in $T = \{0, 1, 2, \dots\}$, or it can be continuous as in $T = [0, \infty)$. Given a probability space $(\Omega, \mathcal{F}, \mathbb{P})$, a classical stochastic process over T is a collection of random variables $\{X_t\}_{t \in T}$ on $(\Omega, \mathcal{F}, \mathbb{P})$ indexed by elements of T . From a practical perspective, one would not start with a given $(\Omega, \mathcal{F}, \mathbb{P})$ but with the specification of a countable collection of finite-dimensional probability distributions $F_{t_1, t_2, \dots, t_n}(C_1, C_2, \dots, C_n) = \mathbb{P}(X_{t_1} \in C_1, X_{t_2} \in C_2, \dots, X_{t_n} \in C_n)$ for any integer $n \geq 1$, any collection of distinct points $t_1, t_2, \dots, t_n \in T$ and any $C_j \in \mathcal{B}(\mathbb{C})$, $j = 1, 2, \dots, n$, which describe the stochastic process. As is well-known, under the Kolmogorov consistency conditions on the finite-dimensional distributions, a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ can

be reconstructed on which the stochastic process $\{X_t\}_{t \in T}$ satisfying all the specifications of the finite-dimensional distributions can be realized; see, e.g., Billingsley (1986).

An equivalent formulation of probability theory in terms of algebras of operators over a Hilbert space, attributed to Gelfand (Streater 2000, Theorem 3.2), is the key to connecting probability theory to quantum mechanics. Consider an essentially bounded random variable X on $(\Omega, \mathcal{F}, \mathbb{P})$, $\text{ess sup}_{\omega \in \Omega} |X(\omega)| < \infty$. Denote the class of all such random variables by $L^\infty(\Omega, \mathcal{F}, \mathbb{P})$. Each element of $L^\infty(\Omega, \mathcal{F}, \mathbb{P})$ may be viewed as a multiplication operator on elements of the Hilbert space $L^2(\Omega, \mathcal{F}, \mathbb{P})$ of square-integrable complex-valued functions on $(\Omega, \mathcal{F}, \mathbb{P})$, in the sense that $X : Y(\cdot) \in L^2(\Omega, \mathcal{F}, \mathbb{P}) \mapsto X(\cdot)Y(\cdot) \in L^2(\Omega, \mathcal{F}, \mathbb{P})$. The class $L^\infty(\Omega, \mathcal{F}, \mathbb{P})$ is closed under the “+” operation ($X_1, X_2 \in L^\infty(\Omega, \mathcal{F}, \mathbb{P}) \rightarrow X_1 + X_2 \in L^\infty(\Omega, \mathcal{F}, \mathbb{P})$) and under the commutative operator composition operation ($X_1, X_2 \in L^\infty(\Omega, \mathcal{F}, \mathbb{P}) \rightarrow X_1 X_2 = X_2 X_1 \in L^\infty(\Omega, \mathcal{F}, \mathbb{P})$). Moreover, an antilinear unary involution operator can be defined on $L^\infty(\Omega, \mathcal{F}, \mathbb{P})$ as $(*) : X \mapsto \bar{X}$. Thus, $L^\infty(\Omega, \mathcal{F}, \mathbb{P})$ forms a commutative $*$ -algebra of operators.

A state μ on a $*$ -operator algebra $\mathcal{A}$ with identity operator $I_{\mathcal{A}}$ (with respect to the composition operation) is a linear complex functional on $\mathcal{A}$ which is positive (i.e., $\mu(A) \geq 0$ for all $0 \leq A \in \mathcal{A}$) and unital, $\mu(I_{\mathcal{A}}) = 1$. A map M acting on $\mathcal{A}$ (such as the state μ) is said to be normal if $M(\sup_{\alpha} A_{\alpha}) = \sup_{\alpha} M(A_{\alpha})$ for any bounded increasing net $\{A_{\alpha}\}$ of positive elements in $\mathcal{A}$. The algebra $L^\infty(\Omega, \mathcal{F}, \mathbb{P})$ is a commutative $*$ -operator algebra on $L^2(\Omega, \mathcal{F}, \mathbb{P})$ (since the composition operation is commutative), and $\mathbb{E}[\cdot]$ is a normal state on this algebra; see, e.g., Bouten et al. (2007) and the references therein. More precisely, the $*$ -algebra is a commutative von Neumann algebra (Bratelli and Robinson 1979; Bouten et al. 2007).

Conversely, it can be shown that any commutative von Neumann algebra $\mathcal{A}$ and a unital normal state μ on $\mathcal{A}$ is $*$ -isomorphic (a bijective correspondence that preserves the involution

operation $*$) to $(L^\infty(\Omega, \mathcal{F}, \nu), \mathbb{E})$, where $\mathbb{E}[\cdot] = \int_\Omega (\cdot)(\omega) \mathbb{P}(d\omega)$ for some probability measure $\mathbb{P}$ on $(\Omega, \mathcal{F})$ which is absolutely continuous with respect to ν . This suggests that a natural generalization of probability theory would be a noncommutative von Neumann algebra $\mathcal{A}$ with identity operator $I_{\mathcal{A}}$ that is endowed with a unital normal state μ ; see Streater (2000) for a historical overview of quantum probability theory. The pair $(\mathcal{A}, \mu)$ is referred to as a *quantum probability space*. If $\mathcal{X} \subset \mathcal{A}$ is a Neumann algebra containing $I_{\mathcal{A}}$, then a positive linear map $E^{\mathcal{X}} : \mathcal{A} \rightarrow \mathcal{X}$ is a conditional expectation map if $\mu(x_1 A x_2) = \mu(x_1 E^{\mathcal{X}}[A] x_2)$ for any $A \in \mathcal{A}$ and $x_1, x_2 \in \mathcal{X}$.

The physical interpretation associated with a quantum probability space is as follows. The underlying Hilbert space of the von Neumann algebra corresponds to the Hilbert space of a quantum mechanical system. The Hermitian elements of the algebra represent physical observables. Orthogonal projection operators in the algebra (operators P satisfying $P^2 = P = P^\dagger$) represent events that can take place, such as the event that “observable X takes on the value c on measurement.” Two events P_1 and P_2 are compatible if they commute; these are events that can be assigned as a joint probability distribution in the classical sense. If the initial state is the density operator ρ , then $\mu(X) = \text{Tr}(\rho X)$ for any observable X . As will be seen next, in a quantum probability space, it is more natural to consider quantum dynamics in the Heisenberg picture, where operators evolve in time and the state is fixed to the initial one.

Let $\mathcal{B}$ and $\mathcal{A}$ be von Neumann algebras with identity operators $I_{\mathcal{B}}$ and $I_{\mathcal{A}}$, respectively, and $(\mathcal{A}, \mu)$ a quantum probability space. A *quantum stochastic process* over $\mathcal{B}$ indexed by $T \subseteq \mathbb{R}$ is a tuple $(\mathcal{A}, \{j_t\}_{t \in T}, \mu)$ where j_t is a $*$ -homomorphism of $\mathcal{B}$ into $\mathcal{A}$ for each $t \in T$ (i.e., $j_t(A^\dagger) = j_t(A)^\dagger$ and $j_t(AB) = j_t(A)j_t(B)$ for any $A, B \in \mathcal{B}$) such that $j_t(I_{\mathcal{B}}) = I_{\mathcal{A}}$ and $\mathcal{A} = \text{vN}(\{j_t(\mathcal{B}), t \in T\})$. Here $j_t(\mathcal{B}) = \{j_t(b), b \in \mathcal{B}\}$ and $\text{vN}(\mathcal{S})$ denotes the von Neumann algebra generated by the operators in $\mathcal{S}$. Since $j_t(X)$ need not commute at different times for any $X \in \mathcal{B}$, one cannot in general assign a joint probability distribution to the process $\{j_t(X)\}_{t \in T}$;

thus it does not have the exact analogue of a collection of finite-dimensional distributions that characterize a classical stochastic process. As a substitute for the finite-dimensional distributions, we introduce finite-dimensional correlation kernels w_{t_n} . For any integer $n \geq 1$, let $\mathbf{b}_n = (b_1, b_2, \dots, b_n) \in \mathcal{B}^n$ with $b_1, b_2, \dots, b_n \in \mathcal{B}$ and $\mathbf{t}_n = (t_1, t_2, \dots, t_n) \in \mathbb{R}^n$, and define $j_{t_n}(\mathbf{b}_n) = j_{t_n}(b_n) \cdots j_{t_2}(b_2) j_{t_1}(b_1)$. Then we define the finite-dimensional correlation kernels as:

$$w_{t_n}(\mathbf{a}_n, \mathbf{b}_n) = \mu(j_{t_n}(\mathbf{a}_n)^\dagger j_{t_n}(\mathbf{b}_n)). \quad (1)$$

One can define a notion of equivalence between two quantum stochastic processes $(\mathcal{A}_k, \{j_{k,t}\}_{t \in T}, \mu_k)$ for $k = 1, 2$ (Accardi et al. 1982, §1). Also, a reconstruction theorem analogous to reconstruction theorems for stochastic processes from finite-dimensional distributions in the classical setting, such as the Kolmogorov extension theorem, can be established (Accardi et al. 1982, Theorem 1.3). Roughly speaking, it states that under certain technical assumptions on w_{t_n} , there exists a quantum stochastic process with w_{t_n} as its correlation kernels, which is unique up to equivalence.

Markov processes are an important and large class of stochastic processes that are employed as models for many applications across diverse fields. Roughly speaking, it is a process where given the present, the future of the process is independent of its past. In the quantum setting, one encounters quantum stochastic processes with an analogous property but properly interpreted since the process generally involves non-commuting operators that do not have a joint probability distribution. They are prominent in quantum optics to model a wide range of situations involving the interaction of localized quantum systems with travelling optical fields and are used to accurately describe many quantum optical devices (Gardiner and Zoller 2004; Nurdin and Yamamoto 2017).

Consider a stochastic process $\{X_t\}$ with $t \in T \subseteq \mathbb{R}$. Then the process is Markov if for any integer $n \geq 2$ and any $t_1, t_2, \dots, t_n \in T$ satisfying $t_1 < t_2 < \dots < t_n$ we have that

$\mathbb{P}(X_{t_n} \in A \mid \sigma(\{X_{t_k}\}_{k=1, \dots, n-1})) = \mathbb{P}(X_{t_n} \in A \mid \sigma(\{X_{t_{n-1}}\}))$ for any $A \in \mathcal{B}(\mathbb{C})$, where $\sigma(Y)$ denotes the σ -algebra generated by the random variables in Y . That is, given a sequence $\{X_{t_k}\}_{k=1, 2, \dots, n-1}$, X_{t_n} only depends on the most recent past, $X_{t_{n-1}}$. Due to noncommutativity, this definition cannot be extended in an analogous way to define a quantum Markov process on a quantum probability space.

To introduce quantum Markov processes, we follow the treatment in Accardi et al. (1982). We start with the definition of canonical maps. Consider a quantum probability space $(\mathcal{A}, \mu)$ and let $\mathcal{A}_{[s,t]} = \text{vN}(\{j_u(\mathcal{B}), s \leq u \leq t \in T\})$, $\mathcal{A}_t = \mathcal{A}_{(-\infty, t]}$, $\mathcal{A}_t = \mathcal{A}_{[t, t]}$ and $\mathcal{A}_t = \mathcal{A}_{[t, \infty)}$. A two-parameter family $\{E_{s,t}\}_{s < t \in T}$ of completely positive identity preserving maps $E_{[s,t]} : \mathcal{A}_t \rightarrow \mathcal{A}_s$ for $s < t \in T$, which are compatible with μ in the sense that $\mu|_{\mathcal{A}_t} = \mu|_{\mathcal{A}_s} \circ E_{s,t}$, $\forall s < t \in T$, is said to be a family of *canonical maps* if they have the properties: (i) $E_{s,t}$ is a normal map and (ii) $E_{s,t}E_{t,u} = E_{s,u}$ for all $s < t < u \in T$. We have the following definition of a quantum Markov process.

Definition 1 (Quantum Markov process)

A quantum stochastic process $(\mathcal{A}, \{j_t\}_{t \in T}, \mu)$ over the von Neumann algebra $\mathcal{B}$ is a quantum Markov process if the canonical maps satisfy $E_{s,t}(\mathcal{A}_{[s,t]}) \subseteq \mathcal{A}_s \forall s < t \in T$.

The definition is slightly relaxed from the one given in Accardi et al. (1982) in that μ is not required to be faithful; only existence of the canonical maps is imposed.

Let j_t have the left inverse $j_t^* : \mathcal{A} \rightarrow \mathcal{B}$ for all $t \in T$ and define $E_{t,t}$ as the identity map on $\mathcal{A}_t$. Then we can define a two-parameter family $\{Z_{s,t}\}_{s < t \in T}$ of completely positive identity preserving maps of $\mathcal{B}$ to itself, defined by $Z_{s,t} = j_s^* E_{s,t} j_t$, $s \leq t \in T$, satisfying $Z_{s,t} Z_{t,u} = Z_{s,u} \forall s \leq t \in T$. In general, $\{E_{s,t}\}$ will not be conditional expectations of $\mathcal{A}_t$ to $\mathcal{A}_s$ unless additional technical conditions, such as from the Tomita-Takesaki theory, are satisfied (Accardi et al. 1982, p. 109). Note, however, that $E_{s,t}$ will be a conditional expectation when $\mathcal{A}$ is a commutative algebra. If we assume that the canonical maps are conditional expectations, then

we have that (Accardi et al. 1982, Theorem 2.1)

$$\begin{aligned} E_{t_0, t_n}(j_{t_1}(a_1)^\dagger \cdots j_{t_n}(a_n)^\dagger j_{t_1}(b_1) \cdots j_{t_n}(b_n)) \\ = j_{t_0} Z_{t_0, t_1}(a_1^\dagger Z_{t_1, t_2}(a_2^\dagger \cdots Z_{t_{n-1}, t_n} \\ (a_n^\dagger b_n) \cdots b_2) b_1), \end{aligned} \quad (2)$$

for any integer $n \geq 1$, any $t_0 \leq t_1 \leq \dots \leq t_n \in T$, and any $a_1, a_2, \dots, a_n, b_1, b_2, \dots, b_n \in \mathcal{B}$. When the canonical maps are also conditional expectations, there exists a one-parameter family $\{E_t\}_{t \in T}$ of conditional expectations mapping $\mathcal{A}$ to $\mathcal{A}_t$ for each $t \in T$, which are compatible with μ , such that $E_{s,t} = E_s|_{\mathcal{A}_t}$ for all $s < t \in T$. In terms of this one-parameter family, the Markov property can be stated as $E_s(\mathcal{A}_s) = \mathcal{A}_s$, $\forall s \in T$. The family $\{E_s\}_{s \in T}$ satisfies the following properties:

$$E_s(ab) = E_s(a)b, \forall a \in \mathcal{A}, b \in \mathcal{A}_s \quad (3)$$

$$\mu = \mu|_{\mathcal{A}_s} \circ E_s \quad (4)$$

$$E_s E_t = E_{s \wedge t}. \quad (5)$$

We can now define quantum Markov processes with conditional expectations, as follows:

Definition 2 $(\mathcal{A}, \{j_t\}_{t \in T}, \mu)$ is a quantum Markov process with conditional expectations if there exists a family of normal conditional expectations $\{E_t\}_{t \in T}$, mapping $\mathcal{A}$ to $\mathcal{A}_t$ for each $t \in T$, satisfying $E_s(\mathcal{A}_s) = \mathcal{A}_s \forall s \in T$ and (3)–(5).

The special structure of quantum Markov processes with conditional expectations entails that their associated multi-time correlation kernels (1) also have a special structure, which will be given in a theorem below. In a slightly different form (to be discussed in the next section), this result is known in the physics literature, in particular in quantum optics, as the “quantum regression theorem.”

Theorem 1 (Quantum regression theorem)

Let $t_n = (t_1, t_2, \dots, t_n) \in T^n$ with $t_1 \leq t_2 \leq \dots \leq t_n$. Then for any integer n , the time-ordered correlation kernels $w_{t_n}(a_n, b_n)$, with $a_n, b_n \in \mathcal{B}^n$, of a quantum Markov process with

conditional expectations are given by:

$$w_{t_n}(\mathbf{a}_n, \mathbf{b}_n) = \mu \circ j_{t_1}(a_1^\dagger Z_{t_1, t_2} a_2^\dagger \cdots Z_{t_{n-1}, t_n} (a_n^\dagger b_n) \cdots b_2) b_1). \quad (6)$$

We will now make the abstract notions presented above explicit by connecting them with concrete quantum Markov models from quantum optics. We consider a localized quantum system with a finite-dimensional Hilbert space $\mathfrak{h}$ coupled to a single propagating optical field. We assume the rotating wave approximation and Markov approximation on the coupling of the system and the field (Gardiner and Zoller 2004). The Hilbert space of the field is the boson (symmetric) Fock space $\mathfrak{F} = \Gamma_s(\mathcal{H})$ over the Hilbert space $\mathcal{H} = L^2(\mathbb{R}_{0+})$ of square-integrable complex functions on $\mathbb{R}_{0+}$; for details see (Hudson and Parthasarathy 1984; Parthasarathy 1992; Meyer 1995). We have the direct-sum decomposition $\mathfrak{F} = \mathbb{C} \oplus \bigoplus_{k=1}^{\infty} \mathcal{H}^{\otimes_s k}$ (where $\otimes_s$ denotes the symmetric tensor product), where $\mathcal{H}^{\otimes_s k}$ is the k -photon subspace. Also, for any positive integer n and $t_0 = 0 < t_1 < t_2 < \dots < t_n < t_{n+1} = \infty$, we have the tensor-product decomposition over time, $\mathfrak{F} = \bigotimes_{k=0}^n \mathfrak{F}_{[t_k, t_{k+1}]}$, where $\mathfrak{F}_{[t_k, t_{k+1}]} = \Gamma_s(\mathcal{H}_{[t_k, t_{k+1}]})$, and $\mathcal{H}_{[t_k, t_{k+1}]} = L^2([t_k, t_{k+1}])$ is the space of square-integrable functions on $[t_k, t_{k+1}]$.

The field has annihilation and creation densities, $b(t)$ and $b^\dagger(t)$, respectively, that satisfy the commutation relation $[b(t), b^\dagger(s)] = \delta(t-s)$ for all $s, t \geq 0$. For any $f \in \mathcal{H}$, let $B(f) = \int_0^\infty \overline{f(s)} b(s) ds$, $B^\dagger(f) = \int_0^\infty f(s) b^\dagger(s) ds$. Then we have the commutation relations, $[B(f), B(g)] = [B^\dagger(f), B^\dagger(g)] = 0$ and $[B(f), B^\dagger(g)] = \int_0^\infty \overline{f(s)} g(s) ds$. Let $|\Phi\rangle$ denote the vacuum state of the field, a state in which the field has no photons. In this state, $b(t)|\Phi\rangle = 0$ for all $t \geq 0$ and thus also $B(f)|\Phi\rangle = 0$. Define $B(t) = B(\mathbf{1}_{[0, t]})$ and $B^\dagger(t) = B^\dagger(\mathbf{1}_{[0, t]})$. Taking f informally as $f = \mathbf{1}_{[t, t+dt]}$, we can define the differentials $dB(t) = B(\mathbf{1}_{[t, t+dt]})$ and $dB^\dagger(t) = B^\dagger(\mathbf{1}_{[t, t+dt]})$. It follows that $dB(t)|\Phi\rangle = 0$, $\langle\Phi|dB(t)dB^\dagger(t)|\Phi\rangle = dt$, and $\langle\Phi|dB^\dagger(t)dB(t)|\Phi\rangle = \langle\Phi|dB(t)dB^\dagger(t)|\Phi\rangle =$

$\langle\Phi|dB^\dagger(t)dB^\dagger(t)|\Phi\rangle = 0$. This informally yields the Itô table in the vacuum state (see Hudson and Parthasarathy 1984; Parthasarathy 1992; Meyer 1995 for a rigorous treatment):

$\times$	dt	dB	dB^*
dt	0	0	0
dB	0	0	dt
dB^*	0	0	0

Take $T = \mathbb{R}_{0+}$ and let the system have Hamiltonian H . If the optical field is initialized in the vacuum state, the joint unitary propagator is given by the solution to a quantum stochastic differential equation (QSDE) (Here we do not consider a general QSDE as we do not include the so-called gauge or exchange process $\Lambda(t)$; see Hudson and Parthasarathy 1984 for details.) (Hudson and Parthasarathy 1984):

$$dU(t) = (-iH + (1/2)L^\dagger L)dt + dB^\dagger(t)L - L^\dagger dB(t)U(t),$$

with $U(0) = I$. Here $L : \mathfrak{h} \rightarrow \mathfrak{h}$ is a bounded system operator through which the system is coupled to the field. Let $\mathfrak{F}_t = \mathfrak{F}_{[0, t]}$ and $\mathfrak{F}_t = \mathfrak{F}_{[t, \infty)}$. Also, let $\mathcal{B}(h)$ denote the space of bounded linear operators over a Hilbert space h . The solution of the QSDE is *adapted*, meaning that for each $t \geq 0$ $U(t) = Z(t) \otimes I_{\mathfrak{F}_t}$ for some $Z(t) \in \mathcal{B}(\mathfrak{h}) \otimes \mathcal{B}(\mathfrak{F}_t)$, where $I_{\mathfrak{F}_t}$ is the identity operator on $\mathfrak{F}_t$. Note that $\mathcal{B}(\mathfrak{h}) \otimes \mathcal{B}(\mathfrak{F}_t)$ is a subalgebra of $\mathcal{B}(\mathfrak{h}) \otimes \mathcal{B}(\mathfrak{F})$ by identifying any element $W \in \mathcal{B}(\mathfrak{h}) \otimes \mathcal{B}(\mathfrak{F}_t)$ with its ampliation $W \otimes I_{\mathfrak{F}_t} \in \mathcal{B}(\mathfrak{h}) \otimes \mathcal{B}(\mathfrak{F})$.

Let $j_t(\cdot) = U(t)^\dagger(\cdot)U(t)$. For any system operator, X and $t \geq 0$, $j_t(X)$ is the evolution of X in the Heisenberg picture. Now, take $\mathcal{B} = \mathcal{B}(\mathfrak{h})$ and let $\mathcal{A}, \mathcal{A}_t$ be as defined previously (in terms of $\mathcal{B}$ and j_t). By the adaptedness of $U(t)$, $\mathcal{A}_t$ can be identified as a subalgebra of $\mathcal{B}(\mathfrak{h}) \otimes \mathcal{B}(\mathfrak{F}_t)$. We will next sketch how $(\mathcal{A}, \{j_t\}_{t \in T}, \mu)$ when μ is a normal state defined by $\mu(\cdot) = \text{Tr}(\rho \otimes |\Phi\rangle\langle\Phi| \cdot)$, where ρ is the initial density operator of the system, defines a quantum Markov process with conditional expectations.

Note that the vacuum state has the decomposition $|\Phi\rangle = |\Phi_t\rangle|\Phi_{[t]}\rangle$, with $|\Phi_t\rangle \in \mathfrak{F}_t$ and $|\Phi_{[t]}\rangle \in \mathfrak{F}_{[t]}$. For each $t \geq 0$, define the operator $E_t : \mathcal{A} \rightarrow \mathcal{B}(\mathfrak{h}) \otimes \mathcal{B}(\mathfrak{F}_{[t]})$ via the identity $\langle \eta' | E_t X | \eta \rangle = \langle \Phi_{[t]} | \langle \eta' | X | \eta \rangle | \Phi_{[t]} \rangle$ for any $X \in \mathcal{A}$ and $\eta, \eta' \in \mathfrak{h} \otimes \mathfrak{F}_{[t]}$ (Parthasarathy 1992, p. 214–215). Via the map E_t , we can then define $E_{[t]} : \mathcal{A} \rightarrow \mathcal{A}_{[t]}$ as $E_{[t]} = E_t \otimes I_{\mathfrak{F}_{[t]}}$. It can be verified that the family $\{E_{[t]}\}$ satisfies (3)–(5) (Parthasarathy 1992, p. 215) and is thus a family of conditional expectations. Furthermore, we can define $E_{s,t} = E_{s[} |_{\mathcal{A}_{[t]}}$ for all $s < t \in T$, and $\{E_{s,t}\}$ is a family of canonical maps.

In the quantum optics setting considered here, we can state the quantum regression theorem in a more explicit form, as it is usually found in the quantum optics literature. From the definition of $E_{s[}$, it is easily verified that $E_{s[}(B(t') - B(t)) = 0$ for any $t' > t > s$. Using this identity and the fact that $E_{s,t} j_t = E_{s[} |_{\mathcal{A}_{[t]}} j_t = E_{s[} j_t$, one can compute $Z_{s,t}(X) = j_s^* E_{s[} j_t(X)$ for any $X \in \mathcal{B}(\mathfrak{h})$ ($0 \leq s \leq t$). The main step is computing the differential (with respect to t , s fixed), $dZ_{s,t}(X) = j_s^* E_{s[} d j_t(X)$; see, e.g., Hudson and Parthasarathy (1984), Parthasarathy (1992) and Meyer (1995). This yields the differential equation

$$\frac{\partial}{\partial t} Z_{s,t}(X) = Z_{s,t}(\mathcal{L}(X)), \quad 0 \leq s \leq t,$$

with initial condition $Z_{s,s}(X) = X$. Here $\mathcal{L}$ the well-known Lindblad super-operator in the Heisenberg picture given by $\mathcal{L}(X) = \frac{1}{2} L^\dagger [X, L] + \frac{1}{2} [L^\dagger, X] L - i[X, H]$. Defining the adjoint map $Z_{s,t}^*$ via the duality $\text{Tr}(Y Z_{s,t}(X)) = \text{Tr}(Z_{s,t}^*(Y) X)$ for all $X, Y \in \mathcal{B}(\mathfrak{h})$, it follows that $Z_{s,t}^*$ satisfies the differential equation (for fixed s)

$$\frac{\partial}{\partial t} Z_{s,t}^*(X) = \mathcal{L}^*(Z_{s,t}^*(X)), \quad 0 \leq s \leq t,$$

with initial condition $Z_{s,s}^*(X) = X$, where $\mathcal{L}^*$ is the Lindblad super-operator in the Schrödinger picture, as the dual to $\mathcal{L}$, given by $\mathcal{L}^*(\rho) = \frac{1}{2} L \rho L_k^\dagger - \frac{1}{2} (L^\dagger L \rho + \rho L^\dagger L) + i[\rho, H]$. This equation has an explicit solution given by $Z_{s,t} = e^{\mathcal{L}^*(t-s)}$ for $t \geq s$. In terms of $Z_{s,t}^*$, the time-ordered correlation kernel (6) can be expressed as

$$w_{t_n}(a_n, b_n) = \text{Tr}(b_n Z_{t_{n-1}, t_n}^* (b_{n-1} \dots Z_{t_2, t_3}^* (b_2 Z_{t_1, t_2}^* (b_1 Z_{t_1, 0}^*(\rho) a_1^\dagger) a_2^\dagger) \dots) a_{n-1}^\dagger) a_n^\dagger). \quad (7)$$

The formula (7) is the familiar form of the quantum regression theorem found in the quantum optics literature (Gardiner and Zoller 2004, §5.2). Note the nested (or pyramidal) structure of (6) and (7) commensurate with the time ordering. This structure is fundamental in quantum theory and reflects the fact that probabilities for the outcomes of sequential measurements on a quantum system (by taking the operators a_k, b_k to be events in the algebra) generally depend on the order in which the measurements are performed; see Gardiner and Zoller (2004, §2.3) and the contribution of Gough in this volume. Also note that for a quantum Markov process with conditional expectations, the time-ordered correlations are completely determined by the reduced evolution on the system (with the field traced out), as given by (6) in the Heisenberg picture or (7) in the Schrödinger picture.

Summary and Future Directions

This review entry has provided a brief introduction to quantum mechanics as a quantum probability theory and the notion of quantum stochastic processes and quantum Markov processes in the quantum probabilistic setting. From the control engineering perspective, quantum probability theory provides a theoretical foundation for the analysis and feedback control of a large class of physical systems with well-defined input and outputs, which are ubiquitous in the field of quantum optics, quantum optomechanics, and superconducting circuits. Such systems are currently of interest as physical platforms for quantum technologies in sensing, communication, and computing.

Readers already familiar with probability theory can use this existing knowledge as a basis for understanding quantum probability theory and its applications. More recent efforts in quantum stochastics include analysis of the dynamics of quantum systems interacting with travelling

fields that are in highly non-Gaussian states such as single-photon states and multiphoton states, cat states, and a class of continuous matrix product states (Gough et al. 2011, 2013, 2012, 2014; Gough and Zhang 2015). An important quantum feedback operation in quantum information processing is quantum error correction (Gottesman 2009; Kerckhoff et al. 2010). Quantum feedback control will become more prominent as technology advances to a stage where more sophisticated quantum error correction codes can be experimentally demonstrated. Control of systems driven by fields in non-Gaussian states for applications such as quantum error correction will be an interesting direction for future research.

Randomized Methods for Control of Uncertain Systems

Fabrizio Dabbene and Roberto Tempo†
CNR-IEIIT, Politecnico di Torino, Torino, Italy

Abstract

In this entry, we study the tools and methodologies for the analysis and design of control systems in the presence of random uncertainty. For analysis, the methods are largely based on the Monte Carlo simulation approach, while for design new randomized algorithms have been developed in the recent years by the systems and control community. These methods have been successfully employed in various application areas, which include systems biology; aerospace control; power systems; control of hard disk drives; high-speed networks; quantized, embedded, and electric circuits; structural design; and automotive and driver assistance.

Keywords

Chernoff bound · Hoeffding inequality · Monte carlo simulation · Randomized algorithms

Introduction

Randomized methods for control deal with the design of uncertain and complex dynamical systems. These methods have been originally developed for linear systems affected by structured uncertainty, usually expressed in the so-called $M - \Delta$ configuration. A similar approach may be followed when dealing with uncertainty in other contexts, such as uncertainty in the environment (random disturbances) or even when there is no uncertainty in the problem formulation, but the complexity of the problem is such that randomized methods may be the best approach, since these methods are known to break the curse of dimensionality; see Tempo et al. (2013) for details.

For the sake of simplicity, in this entry we consider an uncertain linear plant transfer function $P(s, q)$ affected by parametric uncertainty

$$q = [q_1 \dots q_\ell]^T$$

bounded in a set $\mathbb{Q} \subset \mathbb{R}^\ell$. The objective is to design the parameters $\theta \in \mathbb{R}^n$ of a controller transfer function $C(s, \theta)$ so to guarantee robustly some desired performance. This is reformulated as the problem of finding a design satisfying some *uncertain constraints* of the form

$$f(\theta, q) \leq 0 \text{ for all } q \in \mathbb{Q}.$$

In other words, the goal is to design a robust controller which satisfies the uncertain constraints.

Roberto Tempo: deceased.

Specific examples of these constraints include an $\mathcal{H}_\infty$ or $\mathcal{H}_2$ norm bound on the closed-loop sensitivity function or time-domain specifications.

Since this objective may be too hard to achieve in many situations, we are relaxing it as follows: we would like to design controller parameters $\theta \in \mathbb{R}^n$ such that a certain *violation* is allowed, i.e.,

$$\begin{cases} f(\theta, q) \leq 0 & \text{for all } q \in \mathbb{Q}_{\text{good}}; \\ f(\theta, q) > 0 & \text{for all } q \in \mathbb{Q}_{\text{bad}} \end{cases}$$

where the good and bad sets satisfy the equations

$$\begin{cases} \mathbb{Q}_{\text{good}} \cup \mathbb{Q}_{\text{bad}} = \mathbb{Q}; \\ \mathbb{Q}_{\text{good}} \cap \mathbb{Q}_{\text{bad}} = \emptyset, \end{cases}$$

and the goal is to guarantee that the bad set $\mathbb{Q}_{\text{bad}}$ is “small” enough. To state this concept more precisely, we assume that $q \in \mathbb{Q}$ is a random vector with given probability density function (pdf), and we introduce the probability of violation and the controller reliability.

Definition 1 (Probability of Violation and Reliability) The probability of violation for the controller parameters $\theta \in \mathbb{R}^n$ is defined as

$$V(\theta) \doteq \text{Prob} \{q \in \mathbb{Q} : f(\theta, q) > 0\}.$$

The reliability of the design $\theta \in \mathbb{R}^n$ is given by

$$R(\theta) = 1 - V(\theta).$$

In this context, we are satisfied if, given a violation level $\alpha \in (0, 1)$, the probability of violation is sufficiently small, i.e., $V(\theta) \leq \alpha$. We remark that relaxing the requirement of robust satisfaction of the uncertain constraints $f(\theta, q) \leq 0$ to a probabilistic one (by means of the probability of violation) does not help from a computational viewpoint because computing *exactly* the probability $V(\theta)$ is very hard in general, since it requires the solution of a multidimensional integral over the nonconvex domain defined by $f(\theta, q) > 0$, with $q \in \mathbb{Q} \subset \mathbb{R}^\ell$. The problem is then resolved introducing Monte Carlo randomized algorithms (formally defined in the next section). This is a

computational approach which leads to solutions which are often denoted as PAC (probably approximately correct) (Vidyasagar 2002).

More precisely, for fixed design $\theta \in \mathbb{R}^n$, to compute a Monte Carlo approximation based on N random simulations, we consider N independent identically distributed (iid) random samples of $q \in \mathbb{Q}$, called the *multisample*, of the uncertainty q according to the given probability density function

$$q^{(1\dots N)} = \{q^{(1)}, \dots, q^{(N)}\} \in \mathbb{Q}^N.$$

The cardinality N of the multisample $q^{(1\dots N)}$ is often referred to as the *sample complexity* (Vidyasagar 2001). The empirical violation of the design θ is then defined.

We note that in many cases, these samples are available as experimental data, and in this sense, randomized methods can be considered as a data-driven approach. In other situation, the multisample may be the outcome of a random sampling procedure.

Definition 2 (Empirical Violation) For given $\theta \in \mathbb{R}^n$, the empirical violation of $V(\theta, q)$ with respect to the multisample $q^{(1\dots N)} = \{q^{(1)}, \dots, q^{(N)}\} \in \mathbb{Q}^N$ is given by

$$\hat{V}_N(\theta, q^{(1\dots N)}) \doteq \frac{1}{N} \sum_{i=1}^N \mathbb{I}_f(\theta, q^{(i)})$$

where $\mathbb{I}_f(\theta, q^{(i)})$ is the indicator function

$$\mathbb{I}_f(\theta, q^{(i)}) \doteq \begin{cases} 0 & \text{if } f(\theta, q^{(i)}) \leq 0 \\ 1 & \text{otherwise.} \end{cases}$$

Monte Carlo Randomized Algorithms for Analysis

In this section, we study Monte Carlo randomized algorithms for analysis, i.e., when the controller parameters are fixed, and in particular we concentrate on a PAC computation of the probability of violation. In agreement with classical notions in computer science (Mitzenmacher and Upfal

2005; Motwani and Raghavan 1995), a randomized algorithm (RA) is formally defined as an algorithm that *makes random choices* during its execution to produce a result. This implies that, even for the same input data, the algorithm might produce different results at different runs, and, moreover, the results may be incorrect. Therefore, statements regarding properties of these algorithms are necessarily of probabilistic nature.

Formally, the probabilistic parameters ε , $\delta \in (0, 1)$, called *accuracy* and *confidence*, respectively, are introduced. For any θ , the PAC approach provides an empirical violation which is an approximation $\hat{V}_N(\theta, q^{(1\dots N)})$ to $V(\theta)$ within accuracy ε , and this event holds with confidence $1 - \delta$.

Monte Carlo Randomized Algorithm

Given a design $\theta \in \mathbb{R}^n$, a Monte Carlo randomized algorithm (MCRA) is a randomized algorithm that provides an approximation $\hat{V}_N(\theta, q^{(1\dots N)})$ to $V(\theta)$ based on the multisample $q^{(1\dots N)}$. Given accuracy ε and confidence δ , the approximation may be incorrect, i.e.,

$$\left| V(\theta) - \hat{V}(\theta, q^{(1\dots N)}) \right| > \varepsilon$$

but the probability of such an event is bounded, and it is smaller than δ .

In general, the results obtained by an MCRA as well as its running time would be different from one run to another since the algorithm is based on random sampling. As a consequence, the computational complexity of such an algorithm is usually measured in terms of its expected running times. MCRA are efficient because the expected running time is of polynomial order in the problem size (Tempo et al. 2013). One-sided and two-sided Monte Carlo randomized algorithms may also be defined (Tempo and Ishii 2007).

To derive the probabilistic properties of MCRA, we need to state the so-called Hoeffding inequality, which provides a bound on the error between the probability of violation and the empirical violation (Vidyasagar 2002).

Two-Sided Hoeffding Inequality

For fixed $\theta \in \mathbb{R}^n$ and $\varepsilon \in (0, 1)$, we have

$$\text{Prob} \left\{ q^{(1\dots N)} \in \mathbb{Q}^N : \left| V(\theta) - \hat{V}(\theta, q^{(1\dots N)}) \right| > \varepsilon \right\} \leq 2e^{-2N\varepsilon^2}.$$

For fixed accuracy ε , we observe that the right-hand side of this equation approaches zero exponentially. Furthermore, if we bound the right-hand side of this equation with confidence δ , we immediately obtain the classical (additive) Chernoff bound (Chernoff 1952) which is stated next.

Chernoff Bound

For any $\varepsilon \in (0, 1)$ and $\delta \in (0, 1)$, if

$$N \geq \frac{1}{2\varepsilon^2} \log \frac{2}{\delta}$$

then, with probability greater than $1 - \delta$, we have

$$\left| V(\theta) - \hat{V}(\theta, q^{(1\dots N)}) \right| \leq \varepsilon.$$

The Chernoff bound provides an indication of the required sample size, i.e., it provides the so-called sample complexity. More precisely, the sample complexity of a randomized algorithm is defined as the minimum cardinality of the multisample $q^{(1\dots N)}$ that needs to be drawn in order to achieve the desired accuracy ε and confidence δ . Notice that the confidence enters the Chernoff bound in a logarithmic fashion, while accuracy enters quadratically, and therefore, it is much more expensive computationally. Other large deviation inequalities and sample complexity bounds are discussed in the literature, including in particular the (multiplicative) Chernoff bound and the log-over-log bound for computing the so-called empirical maximum (Tempo et al. 1997). We refer to Vidyasagar (2002) for additional details.

Remark 1 (Las Vegas Randomized Algorithms) Las Vegas randomized algorithms (LVRA) are based on random samples generated according to a *discrete* probability density function, instead of a continuous pdf as in the case of Monte Carlo.

Therefore, contrary to MCRA, LVRA provide the “correct answer” with probability one because the entire search space can be fully explored. However, because of randomization, the running time of an LVRA is random (similarly to MCRA) and may be different in each execution. Hence, it is of interest to study the expected running time of the algorithm. It is noted that the expectation is with respect to the random samples generated during the execution of the algorithm and not to the problem data. Classical examples of LVRA within computer science include the well-known randomized quicksort (RQS) algorithm for ranking numbers, which is implemented in a C library of the UNIX operating system (Knuth 1998). Other more recent developments in systems and control regarding these algorithms are for the PageRank computation in the Google search engine (Ishii and Tempo 2010), consensus over large-scale networks (Fagnani and Zampieri 2008), localization and coverage control of robotic networks (Bullo et al. 2012), and opinion dynamics (Frasca et al. 2013). These problems are generally formulated in a graph theoretic setting consisting of nodes and links, and either the nodes or the links are randomly selected according to a given “local” protocol (often called gossip) based on a given discrete pdf.

Randomized Algorithms for Control Design

This section deals with control problems which require computing a design $\theta \in \mathbb{R}^n$ satisfying some probabilistic properties on the uncertain constraints $f(\theta, q)$. Two classes of problems, feasibility and optimization, are considered.

Feasibility Problem

Given uncertain constraints $f(\theta, q)$ and level $\alpha \in (0, 1)$, compute $\theta \in \mathbb{R}^n$ such that

$$V(\theta) = \text{Prob}\{q \in \mathbb{Q} : f(\theta, q) > 0\} \leq \alpha. \quad (1)$$

The second problem relates to the optimization of a linear function of the design parameters under probability constraints.

Optimization Problem

Given uncertain constraints $f(\theta, q)$, a linear objective function $c^T \theta$ and level $\alpha \in (0, 1)$, solve the constrained optimization problem

$$\begin{aligned} \min_{\theta} \quad & c^T \theta \\ \text{subject to} \quad & V(\theta) = \text{Prob}\{q \in \mathbb{Q} : f(\theta, q) > 0\} \\ & \leq \alpha. \end{aligned} \quad (2)$$

Optimization problems subject to constraints of the form $V(\theta) = \text{Prob}\{q \in \mathbb{Q} : f(\theta, q) > 0\} \leq \alpha$ are often called chance constraint optimization (Uryasev 2000).

Most of the algorithms that have been studied in the literature follow two main paradigms and are often based on the following convexity assumption.

Convexity Assumption

The uncertain constraint $f(\theta, q)$ is convex in θ for any fixed value of $q \in \mathbb{Q}$.

The two solution paradigms that have been proposed are now summarized. The algorithms have been implemented in the Toolbox RACT (Randomized Algorithms Control Toolbox) for probabilistic analysis and control design in the presence of uncertainty (Tremba et al. 2008).

Paradigm 1 (Sequential Approach)

Under the convexity assumption, we study the Feasibility Problem (1). The algorithms presented in the literature (see, e.g., Calafiore et al. (2011) for finding a probabilistic feasible design) follow a general iterative scheme (Fig. 1), which consists of successive randomization steps to handle uncertainty and optimization steps to update the design parameters. In particular, these algorithms share two fundamental ingredients:

1. A *probabilistic oracle* which performs a random check, with the objective to assess whether the probability of violation $V(\theta^{(k)})$ of the current candidate solution $\theta^{(k)}$, is smaller than a given level ρ and returns a *certificate* of unfeasibility, that is, a value $q^{(k)}$ such that $f(\theta^{(k)}, q^{(k)}) > 0$, when the candidate solution is found unfeasible

Randomized Methods for Control of Uncertain Systems, Fig. 1 Paradigm for sequential design consisting of probabilistic oracle and update rule

2. An *update rule* ψ_{upd} which exploits the convexity of the problem for constructing a new candidate solution $\theta^{(k+1)}$ based on the probabilistic oracle outcome

In this paradigm, the algorithm returns a design $\hat{\theta}_k$ such that

$$V(\hat{\theta}_k) = \text{Prob} \left\{ q \in \mathbb{Q} : f(\hat{\theta}_k, q) > 0 \right\} \leq \rho$$

is larger than $1 - \delta$. That is, the violation probability associated to the design $\hat{\theta}_k$ is smaller than the level ρ , and this event holds with large confidence $1 - \delta$.

Paradigm 2 (Scenario Approach)

Under the convexity assumption, we study the optimization problem (2). We remark that, even under these assumptions, solving this problem

is very hard computationally because the probabilistic constraint is nonconvex. To alleviate this difficulty, we reformulate problem (2) as a so-called scenario problem introduced in Calafiore and Campi (2006), which is now described.

For randomly extracted scenarios $q^{(1 \dots N)}$, this approach requires computing $\theta \in \mathbb{R}^n$ that solves the convex optimization problem subject to a finite number of sampled constraints

$$\hat{\theta}_N = \min_{\theta} c^T \theta \quad \text{subject to } f(\theta, q^i) \leq 0, \quad i = 1, \dots, N \quad (3)$$

In this paradigm, the algorithm returns in one-shot a design $\hat{\theta}_N$ and the sample complexity N such that

$$V(\hat{\theta}_N) = \text{Prob} \left\{ q \in \mathbb{Q} : f(\hat{\theta}_N, q) > 0 \right\} \leq \rho$$

is larger than $1 - \delta$. That is, the violation probability associated to the design $\hat{\theta}_N$ is smaller than the level ρ , and this event holds with large confidence $1 - \delta$.

Summary and Future Directions

Other probabilistic approaches have been proposed in the literature for control design, which are not based on the convexity assumption. A noticeable example is the strategy based on statistical learning theory (Valiant 1984; Vapnik 1998) which has the objective to design a controller without any convexity assumptions (Alamo et al. 2009). In particular, in Alamo et al. (2013), the general class of sequential probabilistic validation (SPV) algorithms has been introduced. A specific SPV algorithm tailored to scenario problems, providing a sequential scheme for dealing with the optimization problem, has been recently studied in Chamanbaz et al. (2013).

Abstract

When a state variable description of a linear system is known, then its input–output behavior can be easily realized by interconnecting simpler components. The problem of realization is the inverse of this process and can be formulated as follows: given an input–output description, such as the impulse response or the transfer function in the case of time-invariant systems, find a state variable description the impulse response or transfer function of which is the given one. Existence and minimality conditions are discussed. We are interested in realizations of minimum order, which is the case when the

realization is both reachable and observable. Realizations for both continuous-time and discrete-time systems are discussed.

review the key relations between the internal state variable and the external impulse response, or transfer function, descriptions.

Reachability · Observability ·
Irreducibility · Minimality · Realizations

Introduction

The problem of system realization is described as follows. Given an external description of a linear system, specifically its impulse response (or its transfer function in the case of a time-invariant system), determine an internal state variable description that generates the given impulse response (or the transfer function). The name reflects the fact that if a (continuous-time) state variable description is known, an operational amplifier circuit can be easily built to realize (i.e., simulate) the system response. Before discussing the realization problem we

Continuous-Time Linear Systems

Consider a continuous-time system described by the equations

$$\dot{x} = A(t)x + B(t)u, \quad y = C(t)x + D(t)u, \quad (1)$$

where $x(t)$, the state vector, is a column vector of dimension n (i.e., $x(t) \in \mathbb{R}^n$), and $u(t) \in \mathbb{R}^m$ and $y(t) \in \mathbb{R}^p$ are the inputs and outputs of the system. The matrices $A(t) \in \mathbb{R}^{n \times n}$, $B(t) \in \mathbb{R}^{n \times m}$, $C(t) \in \mathbb{R}^{p \times n}$, and $D(t) \in \mathbb{R}^{p \times m}$ have entries which are continuous functions of t . For such a system the output response is given by

$$y(t) = C(t)\Phi(t, t_0)x_0 + \int_{t_0}^t H(t, \tau)u(\tau)d\tau, \quad (2)$$

where $\Phi(t, t_0)$ is the $n \times n$ transition matrix of $\dot{x} = A(t)x$, given by the Peano-Baker formula

$$\Phi(t, t_0) = \begin{cases} I + \int_{t_0}^t A(\sigma_1)d\sigma_1 + \int_{t_0}^t A(\sigma_1) \int_{t_0}^{\sigma_1} A(\sigma_2)d\sigma_2 d\sigma_1 + \cdots & t > t_0, \\ I & t = t_0, \end{cases} \quad (3)$$

$x(t_0) = x_0$ is the initial condition, and $H(t, \tau)$ is the $p \times m$ impulse response matrix given by

$$H(t, \tau) = \begin{cases} C(t)\Phi(t, \tau)B(\tau) + D(t)\delta(t - \tau) & t \geq \tau, \\ 0 & t < \tau, \end{cases} \quad (4)$$

where $\delta(t - \tau)$ is the impulse (delta or Dirac) function applied at time $t = \tau$. Recall that $H(t, \tau)$ denotes the response at time t when an impulse input is applied at time $\tau \leq t$ assuming zero initial conditions.

In the time-invariant case, the equations (1) become

$$\dot{x} = Ax + Bu, \quad y = Cx + Du, \quad (5)$$

and the output response is given by

$$y(t) = Ce^{At}x_0 + \int_0^t H(t, \tau)u(\tau)d\tau, \quad (6)$$

where, without loss of generality, the initial time t_0 has been set to zero. In this case, the impulse response is

$$H(t, \tau) = \begin{cases} Ce^{A(t-\tau)}B + D\delta(t-\tau) & t \geq \tau, \\ 0 & t < \tau. \end{cases} \quad (7)$$

Note that time invariance implies that $H(t, \tau) = H(t - \tau, 0)$, hence τ , which is the time the impulse input is applied to the system, can be set to zero, again without loss of generality, to define $H(t, 0)$. The transfer function of the system is the (one-sided or unilateral) Laplace transform of $H(t, 0)$, namely

$$H(s) = \mathcal{L}[H(t, 0)] = C(sI - A)^{-1}B + D. \quad (8)$$

A realization of $H(t, \tau)$ is any state variable description (1), that is, any quadruple $\{A(t), B(t), C(t), D(t)\}$, the impulse response of which is $H(t, \tau)$, that is, such that (4) is satisfied. Similarly, in the time-invariant case a realization is any quadruple $\{A, B, C, D\}$ such that (7) is satisfied.

In the time-invariant case, a realization is commonly defined in terms of the transfer function matrix $H(s)$. Then a realization of $H(s)$ is any state variable description (5), the transfer function of which is $H(s)$, that is, (8) is satisfied. There are alternative conditions under which a quadruple $\{A, B, C, D\}$ gives a realization of some $H(s)$. To this end, expand $H(s)$ in a Laurent series to obtain

$$H(s) = H_0 + H_1s^{-1} + H_2s^{-2} + \dots \quad (9)$$

The matrices H_i , $i = 0, 1, 2, \dots$ are called the *Markov parameters* of the system and can be determined as follows:

$$H_0 = \lim_{s \rightarrow \infty} H(s), \quad H_1 = \lim_{s \rightarrow \infty} s(H(s) - H_0),$$

and, in general,

$$H_k = \lim_{s \rightarrow \infty} s^k \left(H(s) - \sum_{i=0}^{k-1} H_i s^{-i} \right), \quad k \geq 1.$$

From the definition of Markov parameters, one can conclude that a quadruple $\{A, B, C, D\}$ is a realization of $H(s)$ if and only if

$$H_0 = D, \quad H_i = CA^{i-1}B, \quad i = 1, 2, \dots \quad (10)$$

We now provide conditions for the existence of a realization given either $H(t, \tau)$ or $H(s)$. Note that if a realization does exist then there are infinitely many realizations, as detailed in what follows.

It can be shown that $H(t, \tau)$ is realizable as the impulse response of a system described by the equations (1) if and only if $H(t, \tau)$ can be decomposed as

$$H(t, \tau) = M(t)N(\tau) + D(t)\delta(t - \tau), \quad (11)$$

for $t \geq \tau$, where $M(t)$, $N(t)$, and $D(t)$ are $p \times n$, $n \times m$, and $p \times m$ matrices, respectively, with continuous real-valued entries and with n finite. If in addition to (11), $M(t)$ and $N(t)$ are differentiable and

$$H(t, \tau) = H(t - \tau, 0), \quad (12)$$

then $H(t, \tau)$ is realizable as the impulse response of a system described by the equations (5).

In the time-invariant case, it is more common to work with a given transfer function $H(s)$. Then $H(s)$ is realizable as the transfer function matrix of a time-invariant system described by the equations (5) if and only if $H(s)$ is a matrix of rational functions and satisfies

$$\lim_{s \rightarrow \infty} H(s) < \infty, \quad (13)$$

that is, if and only if $H(s)$ is a *proper rational matrix* or, equivalently, if and only if

$$\lim_{s \rightarrow \infty} H(s) = D, \quad (14)$$

with D constant.

We are interested in realizations (5) of a given transfer function matrix $H(s)$ of least order n (i.e., $A \in \mathbb{R}^{n \times n}$) called minimal or irreducible realizations of $H(s)$. The following two results completely solve the minimal realization problem.

Theorem 1 *An n -dimensional realization $\{A, B, C, D\}$ of $H(s)$ is minimal (irreducible, or of least order) if and only if it is both reachable and observable.*

Note that if (A, B) is not reachable then by separating the reachable and unreachable parts of the system by an equivalence transformation and taking only the reachable part one can still obtain $H(s)$, because the unreachable part of the system does not contribute to $H(s)$. Similar considerations apply with respect to the observability property.

Hence, reachability and observability are necessary conditions for minimality. It can be shown that they are also sufficient.

Theorem 2 *If a minimal realization of order n is found, then any other minimal realization may be obtained via an equivalence transformation.*

Specifically, if $\{A, B, C, D\}$ and $\{\bar{A}, \bar{B}, \bar{C}, \bar{D}\}$ are realizations of $H(s)$ and $\{A, B, C, D\}$ is minimal, then $\{\bar{A}, \bar{B}, \bar{C}, \bar{D}\}$ is also minimal if and only if there exists a nonsingular matrix T such that

$$\begin{aligned}\bar{A} &= TAT^{-1}, & \bar{B} &= TB, \\ \bar{C} &= CT^{-1}, & \bar{D} &= D.\end{aligned}\quad (15)$$

Discrete-Time Linear Systems

The definitions and results for the discrete-time case are completely analogous to the ones for the continuous-time case. They are summarized below for completeness.

Consider a discrete-time system described by the equations

$$\begin{aligned}x(k+1) &= A(k)x(k) + B(k)u(k), \\ y(k) &= C(k)x(k) + D(k)u(k).\end{aligned}\quad (16)$$

Its output response is given by

$$y(k) = C(k)\Phi(k, k_0)x_0 + \sum_{i=k_0}^{k-1} H(k, i)u(i), \quad k > k_0, \quad (17)$$

where $x_0 = x(k_0)$, $\Phi(k, k_0)$ is the $n \times n$ transition matrix, and $H(k, i)$ is the $p \times m$ discrete impulse (pulse) response, that is

$$\Phi(k, k_0) = \begin{cases} A(k-1) \cdots A(k_0) & k > k_0, \\ I & k = k_0, \end{cases} \quad (18)$$

$$H(k, i) = \begin{cases} C(k)\Phi(k, i+1)B(i) & k > i, \\ D(k) & k = i, \\ 0 & k < i. \end{cases} \quad (19)$$

Note that the definition of $\Phi(k, k_0)$ for $k < k_0$ requires invertibility of $A(k)$ for all k .

In the time-invariant case, equations (16) and (17) become

$$\begin{aligned}x(k+1) &= Ax(k) + Bu(k), \\ y(k) &= Cx(k) + Du(k),\end{aligned}\quad (20)$$

and

$$y(k) = CA^k x_0 + \sum_{i=0}^{k-1} H(k, i)u(i), \quad k > 0, \quad (21)$$

where, without loss of generality, k_0 has been set to zero.

The discrete impulse (pulse) response is now given by the equations

$$H(k, i) = \begin{cases} CA^{k-(i+1)}B & k > i, \\ D & k = i, \\ 0 & k < i. \end{cases} \quad (22)$$

Since the system is time invariant, $H(k, i) = H(k-i, 0)$ and i , the time the pulse input is applied, can be set to zero. The transfer function

matrix for (20) is the (one-sided or unilateral) z -transform of $H(k, 0)$, namely

$$H(z) = \mathcal{Z}\{H(k, 0)\} = C(zI - A)^{-1}B + D. \quad (23)$$

It can be shown that a given $p \times m$ matrix $H(k, i)$, with $k \geq i$, is realizable as the pulse response of a system described by the equations (16) if and only if $H(k, i)$ can be decomposed as

$$H(k, i) = \begin{cases} M(k)N(i) & k > i, \\ D(k) & k = i. \end{cases} \quad (24)$$

If, in addition, $H(k, i) = H(k - i, 0)$, then it is realizable via a time-invariant description of the form (20). Similarly to the continuous-time case, $H(z)$ is realizable as the transfer function matrix of a system described by the equations (20) if and only if it is a matrix of rational functions and satisfies

$$\lim_{z \rightarrow \infty} H(z) < \infty. \quad (25)$$

A realization (20) of $H(z)$ is minimal if and only if it is reachable and observable. Finally, if (20) is a minimal realization of $H(z)$, then any other minimal realization is equivalent to (20).

Realization Algorithms

Given a transfer function $H(s)$ (or $H(z)$), we are interested in finding a minimal (irreducible, or of least order) realization of the form (5) (or (20)). First note that there are methods to determine the order n of a minimal realization directly from $H(s)$, via the characteristic polynomial and notions such as the McMillan degree of $H(s)$ or via the Markov parameters of $H(s)$ and the Hankel matrix. This can be done without finding a minimal realization. Knowing the order of a minimal realization in advance is useful as it provides a guide as to what we should expect when we determine an actual realization. Details may be found in the references provided.

In special cases it is possible that the realization algorithm results directly in a reachable and observable, and therefore minimal, realization. It is more common, however, for the algorithm to result in a realization that is either reachable or observable, but not both. In such cases, an extra step is needed to isolate the unreachable/unobservable part of the realization and take only the part that it is both reachable and observable. The reader should consult any of the references for detailed descriptions of several realization algorithms.

To illustrate the above discussion we present a simple example. Consider the transfer function

$$H(s) = \frac{b_2 s^2 + b_1 s + b_0}{s^3 + a_2 s^2 + a_1 s + a_0}$$

and assume that numerator and denominator are coprime, that is, they do not have common roots. A realization is given by the matrices

$$A = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ -a_0 & -a_1 & -a_2 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix},$$

$$C = [b_0, \quad b_1, \quad b_2], \quad D = [0].$$

This realization is reachable (the pair (A, B) has a form called *controller form*) and observable and, therefore, it is a minimal realization of $H(s)$. This algorithm easily generalizes to the case in which the degree of the denominator of $H(s)$ is n (in this example it is 3). Note that if $\lim_{s \rightarrow \infty} H(s) = D \neq 0$, then one has to apply the previous algorithm to $\hat{H}(s) = H(s) - D$ to obtain A , B , and C .

Summary

The state variable realization of impulse responses and transfer functions was one of the early problems addressed by system theory. Its solution provides clear understanding of the relations between external (input-output) and internal descriptions of systems. A key result is that any minimal order realization is controllable and observable. Many realization algorithms

may be found in the literature. Extensions to polynomial matrix descriptions can also be found in the literature, as well as extensions to partial realizations.

Recommended Reading

A clear understanding of the relationship between external and internal descriptions of systems is one of the principal contributions of systems theory. This topic was developed in the early 1960s with original contributions from Gilbert (1963) and Kalman (1963). The role of controllability and observability in minimal realization is due to Kalman (1963); see also Kalman et al. (1969). For extensive historical comments, see Kailath (1980). The time-varying case is treated in Brockett (1970), Antsaklis and Michel (2006), and Rugh (1996).

Real-Time Optimization of Industrial Processes

Jorge Otávio Trierweiler

Group of Intensification, Modelling, Simulation, Control and Optimization of Processes (GIMSCOP), Department of Chemical Engineering, Federal University of Rio Grande do Sul (UFRGS), Porto Alegre, RS, Brazil

Abstract

RTO aims to optimize the operation of the process taking into account economic terms directly. There are several fundamental gears for smooth operating of an RTO solution. The RTO loop is an extension of feedback control system and consists of subsystems for (a) steady-state detection, (b) data reconciliation and measurement validation, (c) process model updating, and (d) model-based optimization followed by solution validation and implementation. There are several alternatives for each one of these subsystems. This contribution introduces some of the currently used approaches and gives some perspectives for future works in this area.

Introduction

Effectiveness, efficiency, product quality, process safety, and low environmental impact are the main driving forces for the improvement of the operation of industrial processes. Real-time (or online) optimization (RTO) is one of the options that are available to achieve these goals and is attracting considerable industrial interest due to its direct and indirect benefits.

RTO systems are model-based, closed-loop process control systems whose objective is to maintain the process operation as nearly as possible to the optimal operating point. Such RTO systems use rigorous process models and current economic information to predict the optimal process operating conditions. Additionally, RTO can mitigate and reject long-term disturbances and performance losses (e.g., due to fouling of heat exchangers or deactivation of catalysts).

The direct benefit from applying RTO is improving the economic performance in terms of increasing the profit of the plant and reducing energy consumption and pollutant emissions. These are also called the *online benefits*. The indirect benefits result from the tools used in the implementation of RTO. For instance, a better understanding of the processes can be employed to debottleneck the plant and to reduce operating difficulties. In addition, abnormal measurement information obtained from gross error detection can help instrumentation and process engineers to troubleshoot the plant instrument errors. Parameter estimation is very useful for process engineers to evaluate the equipment conditions and to identify decreasing efficiencies and other sources of problems. Furthermore, the detailed process simulation of the model used in online optimization can be used for process monitoring and serve as a training tool for new operators. Finally, the rigorous process model can be used for process maintenance, advanced process control, process design, facility planning, and process monitoring.

Real-time optimization (RTO) solutions have been developed since the early 1980s, and nowadays there are many petrochemical and chemical applications, especially in the production of

ethylene and propylene in fluid catalytic cracking units (FCCUs) (Darby et al. 2011). Other successful industrial applications are mentioned in Alkaya et al. (2009) with the respective economic returns.

Control Layers and the RTO Concept

Usually the process control is stratified into several layers, which have different response times and control objectives. RTO is located in an intermediate layer that provides the connection between plant scheduling (medium-term planning) and the control system (short-term process performance). In a plant control hierarchy, process disturbances are controlled using process controllers, whereas the RTO system must track changes in the optimum operating conditions caused by low-frequency process changes (e.g., raw material quality and composition, catalyst deactivation).

The typical structure of an RTO system is shown in Fig. 1, which depicts the elements of the closed-loop system. The RTO loop is an extension of the feedback control system and consists of subsystems for (a) steady-state detection, (b) data reconciliation and measurement validation, (c) process model updating, and (d) model-based optimization followed by solution validation and implementation. Once the plant operation has reached a steady state, the plant data ($y = [Y_e, Y_s, Y_r]$) are gathered and validated to detect and correct gross errors in the process measurements, and at the same time the measurements may be reconciled using material and energy balances to ensure that the data set used for model updating is consistent. These validated measurements are used to estimate model parameters (θ) to ensure that the model represents the plant faithfully at the current operating point. Then, the optimum controller set points (Y_{sSET}) and manipulated targets ($U_{TARGETS}$ and $U_{eTARGETS}$) are calculated using the updated model and are transferred to the advanced process controllers after they have been validated to be effectively applied.

Real-Time Optimization of Industrial Processes, Fig. 1 Basic structure of the traditional RTO

Each layer in Fig. 1 has its own specific tasks as discussed in the following:

1. **Regulatory layer.** This layer is focused on basic (e.g., temperature, flow rate) and inventory (e.g., level and pressure) control ensuring safety and operational stability for the industrial plant. The holdups of vapors and gases are measured by pressure sensors, while the holdups of liquids and solids are measured by level and weighing sensors. In the case of unstable processes, the regulatory layer is also responsible for their stabilization, e.g., by temperature control of industrial reactors. No industrial process can operate without this control layer. The typical operation time scan is in the order of seconds. For its design, typical questions that have to be answered are the following: “How to ensure safe unit operation?” “How to quickly meet the demands coming from the supervisory layer or from the operators?” “How to prevent disturbances to propagate throughout the plant?” The control technology that prevails in this layer is SISO (single-input-single-output) PID controllers, with very few cases

where the derivative action is effectively employed. In Fig. 1, Y_r are the controlled variables of this layer (e.g., levels, flow rates, pressures, temperatures, pH), and U_r are the corresponding manipulated variables, typically control valves.

2. **Supervisory layer.** This layer is concerned with the quality of the final product. The goal is to ensure the specifications without infringing the operating limits of the equipment. Typically, in this layer there is a strong interaction between the controlled variables, requiring tailored multi-look control structures or the use of multivariate control techniques. The dominant advanced technology in this layer is model predictive control (MPC). In this layer the calculations and updates are performed on the time scale of minutes and the typical associated question is “how to ensure the quality of the final product while satisfying the operating constraints and improving the profitability by reducing the variability of the product parameters?” Here the controlled variables (Y_s) are usually related to the product quality and the manipulated variables are the set points for the regulatory layer Y_{rSET} and additional

manipulated variables (Us) not used by the regulatory layer (e.g., variable frequency drive).

3. **RTO layer.** Here the main focus is the profitability of the process. Specifications and operating points (i.e., set points and targets for the manipulated variables) are determined by solving an optimization problem that aims at maximizing the profitability of the process under stationary conditions. When the optimal operating point is close to the operational limits, the real-time optimization is quite straightforward, since it is enough to take the process to these limits, which is usually done by solving a linear programming (LP) optimization problem. Such simple solutions are effective especially in cases where it is known that to maximize or to minimize the flow rate of a given stream will maximize the profitability. As this kind of solution can be easily implemented, most commercial predictive controllers already have an LP or QP layer integrated, using as a model the gain of the dynamic model used in the MPC. However, for processes with large recycling streams and pronounced nonlinearity, this type of solution is not enough to bring the system to its optimal operating conditions. In this case, it is essential to use a nonlinear optimizer that aims at driving the system to operate in the best operating region. When the industrial process works essentially in steady state, the problem can be solved using stationary models. The solutions offered on the market typically involve the use of a stationary process simulator (e.g., Aspen Plus, PRO II). The RTO sampling times are in the time scale of hours and the questions to be answered are the following: “What is the best way of operation?” “How to increase the profitability of the process?” “How to decrease energy consumption and to increase the process efficiency?”

Four Elements of Classical Real-Time Optimization

A standard RTO solution requires that all four calculation blocks illustrated in Fig. 1 work

together smoothly. In fact, each block can be formulated as an optimization problem by itself. Sometimes these optimization problems are combined together. Below the alternative techniques that can be applied to each of these subsystems are discussed.

Steady-State Detection (SSD)

As indicated in Fig. 1, the RTO loop execution begins with the detection of a steady state. Identifying a steady state may be difficult because process variables are noisy and measurements do not settle at a constant value. Being at a steady state can be defined as an acceptable constancy of the measurements over a given period of time. Therefore, tests for stationarity are commonly based on checking the constancy of the measured quantities.

Mejía et al. (2010) compared 6 different approaches to SSD using 5,760 simulated data sets. They concluded that the method based on the estimation of the absolute value of the first and the second derivatives defined by

$$I_{DER} = \left| \frac{\widehat{dy}}{dx} \right| + 10 \left| \frac{\widehat{d^2y}}{dt^2} \right| \quad (1)$$

gives the best results. Although this idea is quite simple, as being at a steady state means zero derivatives by definition, it has some implementation issues, due to signal noise and outliers. These problems can be reduced by smoothing the plant data using smoothing splines, noncausal Butterworth filters, or wavelet decompositions. The second best compared approach was the local autocorrelation (Mejía et al. 2010) followed by the two statistical nonparametric tests of independence hypothesis proposed by Bebar (2005) and by the method of Cao and Rhinehart (1995).

Data Reconciliation (DR)

Within the mathematical models of industrial processes, the balance equations that result from conservation laws of mass, energy, etc., are the core that cannot be subject to debate. If the measured data do not satisfy the balance equations, this fact must be attributed to measurement errors or to fundamental model inadequacies. Ruling

out the latter, as measurement errors are always present, before using the measured data, they should be adjusted to obey the conservation laws and other constraints, e.g., of their ranges. The adjustment using optimization techniques combined with the statistical theory of errors is called data reconciliation. Unfortunately the adjustment of all variables can be greatly affected by “gross errors” in one variable, so such errors must be detected.

The relationship between a measurement of a variable and its true value can be represented by

$$y_m = y + \overbrace{e_r + e_g}^{\text{error}} \quad (2)$$

where y_m and y are the measured and true values, while e_r and e_g are the random and gross errors, respectively. The random errors (e_r) are assumed to be zero mean and normally distributed (Gaussian), since they are the result of the simultaneous effect of several causes. The gross errors (e_g) are caused by large nonrandom events. They can be subdivided into measurement-related errors, such as malfunctioning sensors (e.g., incorrect calibration, sensor degradation, or damage to the electronics), and processes-related errors, such as process leaks.

In the absence of gross errors, the simplest version of data reconciliation can be stated as a quadratic programming (QP) problem

$$\min_y \frac{1}{2} (y - y_m)^T Q^{-1} (y - y_m) \quad (3)$$

subject to the linear or linearized constraint related to the process model, written as

$$A \cdot y - c = 0.$$

The covariance matrix (Q), which is usually diagonal, captures the variance of the sensors and is responsible to distribute the errors among the measurements (y_m). The solution of this problem is the reconciled value that for this simple case is given analytically by

$$y = \left[I - QA^T(AQA)^{-1}A \right] y_m + QA^T(AQA)^{-1}c.$$

A rigorous formulation of the reconciliation problem is possible even with nonlinear constraints; only the general existence and uniqueness of a solution is not warranted theoretically.

Several statistical tests have been constructed for the detection of gross errors. Some of them are based in the distribution of the constraint residuals, i.e., $r_c = A \cdot y_m - c$, and others are based on the distribution of the estimated error after the reconciliation procedure, i.e., $\hat{e} = y_m - y$. The evaluation of r_c does not require solving previously the associated data reconciliation problem. For a complete discussion and review, see Narasimhan and Jordache (1999) and Sequeira et al. (2002).

Model Updating

A key, yet difficult, decision in model parameter adaptation is to select the parameters that are adapted. These parameters should be identifiable and represent actual changes in the process, and their adaptation should help to approach the true process optimum. Clearly, the smaller the subset of parameters, the better the confidence in the parameter estimates and the lower the required excitation (also the better the regularization effect). But too few adjustable parameters can lead to misleading models and thus wrong proposals for operational changes.

In general, the parameter estimation and updating are limited not only by the lack of information available from experimental data but also by the correlation between the parameters that are identified. The estimation of correlated parameters leads to a high degree of uncertainty in the model, since different combinations of parameter values lead to the same value of the objective function in the estimation problem.

The selection of the right number of parameters to be identified can be done by the analysis of the sensitivity matrix (S). The elements of S , s_{ij} , are the partial derivatives of the measurement y_i

with respect to the parameter θ_j evaluated at the current value of the parameter (θ_0), i.e.,

$$s_{ij} = \left(\frac{\partial y_i}{\partial \theta_j} \right) \Big|_{\theta=\theta_0}. \quad (4)$$

In general, different parameters and measurements have distinct magnitudes. Therefore, scaling is a key issue that has a strong impact on the results. Traditionally each element of the matrix S is scaled by the initial guess θ_{0j} of the parameter and by the average value of the measurement i ($\bar{y}_{si}$). The scaled elements $s_{s,ij}$ are then given by

$$s_{s,ij} = \left(\frac{\theta_{0j}}{\bar{y}_{si}} \right) \left(\frac{\partial y_i}{\partial \theta_j} \right) \Big|_{\theta=\theta_0} \quad (5)$$

This scaling procedure has some problems, once it requires both a good initial guess for the parameters and representative average values for the measurements. But the main drawback is that it does not consider the multivariable nature existing among all parameters and outputs. To solve these drawbacks, Botelho et al. (2012) proposed to apply diagonal scaling matrices L and R that result from the solution of the convex optimization problem to find the minimized condition number of the sensitivity matrix, $\gamma(LSR)$, i.e.,

$$\begin{aligned} \min_{L,R} \gamma(LSR) \\ \text{s.t. } L \in \mathbb{R}^{n_y \times n_y}, \text{ diagonal and nonsingular} \\ R \in \mathbb{R}^{n_\theta \times n_\theta}, \text{ diagonal and nonsingular} \end{aligned} \quad (6)$$

This convex optimization problem can be solved using the LMI (linear matrix inequality) approach as described by Boyd et al. (1994). With the optimized scaling matrices L and R , the scaled sensitivity matrix S_s is given by

$$S_s = LSR \quad (7)$$

With S_s , the best subset of parameters to be estimated can be determined using the non-square relative gain array matrix (NSRGA) as also proposed by Botelho et al. (2012). The NSRGA

can be easily calculated for the scaled sensitivity matrix by

$$NSRGA(S_s) \stackrel{\text{def}}{=} S_s \circ (S_s^\dagger)^T \quad (8)$$

where $(S_s^\dagger)^T$ is the transpose of the pseudo-inverse of S_s and $\circ$ is the entrywise product (also known as the Hadamard or element-wise product). The rows of $NSRGA(S_s)$ are related to the output measurements, whereas the columns are related to the parameters. The sum of the values in each column, whose values can vary between 0 and 1, reflects the relevance of each parameter, and it can be used to sort in descending order their influence on the outputs. When the sum of a column is close to 1, the corresponding parameter has a small correlation with the other ones and a strong influence on the output measurements.

Figure 2 illustrates the typical ordering produced by sorting the $NSRGA(S_s)$ in descending order. Thus, it is possible to have an idea of which parameters should be selected for estimation. The values presented in this figure suggest that the parameters $P11$ and $P4$ have very small correlation with the others and should be selected as updated parameters, whereas the parameters $P12$ and $P1$ show the opposite behavior and should not be updated.

Solving the Optimization Problem

Nonlinear programs for RTO can be formulated using models of different complexities. For example, RTO can be based on process models similar to those used for design and analysis, using commercial simulators (e.g., Aspen Plus, PRO II, HYSYS, etc.). On the other hand, because these problems need to be solved at regular intervals (at least every few hours), detailed simulation models can be partly replaced by correlations or operating curves that are fitted to the process and updated on a longer time scale.

If a rigorous process model is used, the number of nonlinear equations can be very large. The model is usually built by linking smaller sub-models. The optimization problem can be formulated as the following nonlinear programming problem (NLP):

Real-Time Optimization of Industrial Processes, Fig. 2 Illustrative example of using $NSRGA(S_s)$ to rank the parameters

$$\begin{aligned}
 & \min_{x_M, S_M} f(x_M, S_M) \\
 & \quad s.t. \\
 & M_1(x_{M1}, S_{M1}; \theta_{M1}) = 0 \\
 & \quad \vdots \\
 & M_n(x_{Mn}, S_{Mn}; \theta_{Mn}) = 0 \\
 & OC(x_M, S_M) \leq 0 \\
 & x_M = [x_{M1}, \dots, x_{Mn}], S_M = [S_{M1}, \dots, S_{Mn}],
 \end{aligned} \tag{9}$$

where M_i are the unit modules that can be solved by a tailored procedure in the modular approach or all together in the equation-oriented approach. Each unit model M_i has internal variables x_{Mi} and parameters θ_{Mi} . These unit models are connected by the input and output streams S_{Mi} . Additionally, there are operating constraints OC to capture the possible lower and upper bounds and other equipment constraints. The objective function $f(x_M, S_M)$ is based on an economic model that involves the raw materials, products, and operating costs.

Successive quadratic programming (SQP) has become the most popular method for solving these nonlinear constrained optimization problems. SQP converges the equality and inequality constraints simultaneously with the optimality conditions. This strategy requires relatively few function evaluations and often performs efficiently for process optimization problems. The NLP solver can be implemented in a nonintrusive

way, similar to recycle convergence modules that are already in place. As a result, the structure of the simulation environment and the unit operation blocks does not need to be modified in order to include the optimization, so that SQP can be easily incorporated within existing modular simulators and therefore be applied directly to flow sheets modeled in these commercial simulators. However, in this case derivative information must be obtained by numerical differentiation which increases the effort and slows down convergence near the optimum.

For fully equation-oriented models with the exact first and second derivatives for all constraints and objective functions, efficient NLP algorithms were developed. For instance, large equation-based models can be solved efficiently with structured barrier NLP solvers (see Biegler 2010 for a detailed overview). But for problems where function evaluations are expensive, and gradients and Hessians are difficult to obtain, it is not clear that large-scale NLP solvers should be applied. Black-box optimization models with inexact (or approximated) derivatives and few decision variables are poorly served by large-scale NLP solvers, and derivative-free optimization algorithms should be considered instead. For the standard RTO problems formulated using modular process simulator model, SQP and

reduced-space SQP methods are expected to perform well (see Biegler 2010; Alkaya et al. 2009 for detailed discussion).

After solving the RTO optimization problem, it is necessary to decide if the solution can be implemented. For this, it is necessary to verify if the dominant cause of the plant changes is noise, since in this case implementing these changes could lower the profit. Thus, an important challenge in RTO results analysis is to determine when to implement the calculated changes (Miletic and Marlin 1996).

Summary and Future Directions

RTO aims at optimizing the operation of the process taking into account economic terms directly. There are several fundamental needs for a smooth operation of an RTO solution. The central point is the mathematical modeling which can be a complex first principle model or be based on simple operating curves. If a good model is available, it is necessary to have a good characterization of the inlet streams (properties and composition), to employ data reconciliation and gross error detection and steady-state identification. Finally, the efficiency of the optimizer is a key issue. Due to the time and resources needed to implement and maintain an RTO solution, a full RTO project involves a certain high risk. Therefore, in cases where simpler and easier approaches can be applied with equivalent economic benefits, they should be used instead. For processes with large recycle streams, it is worthwhile to apply the classical RTO strategy, i.e., the one discussed in the last section. In this case the optimal solution is not trivial, once it is not simply the maximal capacity of the plant. For the cases where the optimal operating constraint is a direct consequence of the operating process capacity, the economic optimization can be easily included in the LP or QP layer implemented usually within a model predictive controller.

In the previous section, the so-called two-step approach, where the measurements are used to refine the process model, which is then used to

repeat the optimization, was described. Several RTO schemes have emerged since the development of this two-step approach in the 1970s. Recently, it has been proposed to update the model differently. Instead of adjusting the model parameters, one updates correction terms that are added to the cost and constraint functions of the optimization problem. The technique, labeled as modifier adaptation (RTO-MA), forces the modeled cost and constraints to match the plant values (Marchetti et al. 2009; Gao and Engell 2005). The main advantage of RTO-MA compared to the two-step approach lies in its ability to converge to the true plant optimum, even in the presence of structural plant-model mismatch. RTO-MA is a static optimization method which means that its application to a continuous process requires waiting for reaching the steady state before taking measurements, updating the correction terms, and repeating the numerical optimization. Hence, several iterations are generally required before convergence can be achieved. In contrast, implicit methods, such as self-optimizing control (Skogetstad 2000) and NCO tracking (François et al. 2005), propose to adjust the inputs online in a control-inspired manner. Especially simple to be implemented is the “self-optimizing” approach, where a feedback control structure is chosen so that maintaining some function of the measured variables constant automatically maintains the process near an economically optimal steady state in the presence of disturbances. The problem is posed from a plantwide perspective, since the economics are determined by overall plant behavior.

The classical steady-state RTO has some drawbacks related to its low frequency of execution. It is normally run twice or three times per day and one does not consider the cost of transiting from one operating condition to another. Some plants need to respond to market changes very quickly, like grade changes in polymerization and petroleum process. In these processes, market competition requires the capability to accommodate fast and cost-effective transitions so that companies can produce and sell on demand at favorable prices. To provide this capability, dynamic RTO is

being developed and implemented in industrial processes. The largest difference between steady-state and dynamic RTOs is that traditional RTO only provides optimal operating conditions at the steady state, while dynamic RTO provides a trajectory of changes of operating conditions. Dynamic RTO does not require steady-state conditions to be applied. The formulation and solution of the problem DRTO are very similar to the approach used to solve nonlinear predictive controllers (NMPC), with the primary difference the inclusion of economic aspects in the objective function (Engell 2007).

Recommended Reading

As a number of design decisions must be made in the construction of a RTO system, there is no single approach how to implement it. The elements of the solution were discussed here which should be viewed as a starting point for further reading. The review paper by Engell (2007) discusses and compares several approaches for RTO and DRTO giving a quite general and broad perspective of the area. For the reader interested more in the solution and formulation of the optimization problems, the book by Biegler (2010) is a very good starting point and gives a complete discussion about the solvers currently used, illustrating the application with several examples. For data reconciliation and gross error detection the book by Narasimhan and Jordache (1999) is a good starting point. Finally, an industrial discussion about RTO and alternative approaches that have been used in the industry can be found in Darby et al. (2011).

Università degli Studi di Cassino e del Lazio
Meridionale, Cassino (FR), Italy

Abstract

Redundancy may occur in different ways in a robotic system. This article focuses on the resolution of kinematic redundancy, i.e., on the techniques for exploiting the redundant degrees of freedom in the solution of the inverse kinematics problem; this is indeed an issue of major relevance for motion planning and control purposes.

Keywords

Redundancy · Task-oriented kinematics · Kinematic singularity · Algorithmic singularity · Optimization · Task-space augmentation

Introduction

Redundant robots possess more resources than those strictly required to execute their task; this provides the robot with an increased capacity of facing real-world applications by allowing to handle performance issues besides the mere achievement of a given motion trajectory.

Redundancy may occur in the sensory system, in the mechanical structure, and/or in the actuation system, thus allowing, e.g., fault accommodation, multisensory perception,

dexterous motion, and load sharing. Nevertheless, unless otherwise specified, by *redundant robot* it is meant a robot that has a kinematically redundant mechanical structure, i.e., provided with more degrees of freedom than those strictly required to execute its task; this also typically leads to a redundancy in the number of actuators and sensors. Noticeably, *kinematic redundancy* is usually the key to handle the avoidance of singular configurations, the occurrence of joint limits, the engagement of obstacles in the workspace, and the minimization of joint torques or energy. In practice, if properly managed, the increased dexterity characterizing kinematically redundant robots may allow them to achieve a higher degree of autonomy.

In principle, no robot is inherently redundant; rather, there are certain tasks with respect to which it may become redundant. Nevertheless, since most papers in the classical literature on the topic have dealt with robotic manipulators (for which a general task consists in tracking an end-effector motion trajectory requiring six degrees of freedom), a robot arm with seven or more joints is often considered as a typical example of an inherently redundant manipulator. However, even robot arms with fewer degrees of freedom, like conventional six-joint industrial manipulators, may become kinematically redundant for specific tasks, such as simple end-effector positioning without constraints on the orientation.

In the case of traditional industrial applications involving non-redundant mechanical structures, the occurrence of singular configuration and/or the presence of obstacles in the workcell resulted in the need of a carefully structured (and static) working space where the motion of the manipulator could be planned in advance.

On the other hand, the presence of redundant degrees of freedom allows motions of the manipulator that do not displace the end effector (the so-called *self-motions* or *internal motions*); this implies that the same end-effector task can be executed with several different joint motions, giving the possibility of better exploiting the workspace of the manipulator and ultimately resulting in a more versatile robotic arm (see Fig. 1). Such feature is a key to allow

Redundant Robots, Fig. 1 A self-motion of the arm that keeps the end-effector position at the blue spot. It is possible to choose configurations that both take the blue spot and avoid the red obstacle

operation in unstructured and/or dynamically varying environments that characterize advanced industrial applications and service robotics scenarios.

The biological archetype of a robotic manipulator is the human arm, which, not surprisingly, also inspires the terminology used to characterize the serial-chain structure of a robot *arm*. Remarkably, a simple look at the human arm kinematics from the torso to the hand allows to recognize seven degrees of freedom (three at the *shoulder*, one at the *elbow*, and three at the *wrist*) that make a manipulator kinematically redundant.

The kinematic arrangement of the human arm has been replicated in a number of robots often termed as *human-arm-like manipulators* (see, e.g., Fig. 2). Manipulators with a larger number of joints are often called *hyperredundant robots* and include – among others – snakelike robots (Fig. 3).

The use of two or more robotic structures to execute a task (as in the case of cooperating manipulators or multifingered hands or multiarm/multilegged robots) also gives rise to kinematic redundancy. A headed multilimb structure is typical of a humanoid robot (Fig. 4). Redundant mechanisms also include vehicle-manipulator systems (Fig. 5).

Although the realization of a kinematically redundant structure raises a number of issues from the point of view of mechanical design, this article focuses on the techniques for exploiting

R

the redundant degrees of freedom in the solution of the inverse kinematics problem. This is an issue of major relevance for motion planning and control purposes.

Task-Oriented Kinematics

The relationship between the N variables representing the configuration $\mathbf{q}$ of an articulated manipulator in the *joint space* and the M variables describing an assigned task $\mathbf{t}$ in an

Redundant Robots, Fig. 4 The Honda Asimo

Redundant Robots, Fig. 5 The KUKA youBot

appropriate *task space* constitutes a task-oriented kinematics; this can be established at the position, velocity, or acceleration level. Typically, one has $N \geq M$, so that the joints can provide at least the degrees of freedom required for the end-effector task. If $N > M$ strictly, the manipulator is *kinematically redundant*.

At the position level, the *direct kinematics* equation takes on the form

$$\mathbf{t} = \mathbf{k}_t(\mathbf{q}), \quad (1)$$

where $\mathbf{k}_t$ is a nonlinear vector function.

Besides the direct kinematics expressed at the position level, it is useful to consider the *first-order differential kinematics* (Whitney 1969)

$$\dot{\mathbf{t}} = \mathbf{J}_t(\mathbf{q}) \dot{\mathbf{q}}, \quad (2)$$

that can be obtained by differentiating Eq. (1) w.r.t. time. In (2), the mapping between the task-space and the joint-space velocities is held by the $M \times N$ *task Jacobian* matrix $\mathbf{J}_t(\mathbf{q}) = \partial \mathbf{k}_t / \partial \mathbf{q}$ (also called *analytic Jacobian*).

Remarkably, $\dot{\mathbf{t}}$ expresses the rate of change of the variables adopted to describe the task and thus does not necessarily have the meaning of an end-effector velocity. In general, by denoting the end-effector spatial velocity $\mathbf{v}_N$ as the stack of the 3D translational and angular end-effector velocities, the following relationship holds

$$\dot{\mathbf{t}} = \mathbf{T}(\mathbf{t}) \mathbf{v}_N, \quad (3)$$

where $\mathbf{T}$ is an $M \times 6$ transformation matrix.

For a given manipulator, the mapping

$$\mathbf{v}_N = \mathbf{J}(\mathbf{q}) \dot{\mathbf{q}} \quad (4)$$

relates a joint-space velocity to the corresponding end-effector velocity through the $6 \times N$ *geometric Jacobian* matrix $\mathbf{J}$.

By comparing (2), (3), and (4), the relation between the geometric Jacobian and the task Jacobian can be found as

$$\mathbf{J}_t(\mathbf{q}) = \mathbf{T}(\mathbf{t}) \mathbf{J}(\mathbf{q}). \quad (5)$$

Further differentiation of (2) w.r.t. time provides the following relationship between the acceleration variables

$$\ddot{\mathbf{t}} = \mathbf{J}_t(\mathbf{q}) \ddot{\mathbf{q}} + \dot{\mathbf{J}}_t(\mathbf{q}, \dot{\mathbf{q}}) \dot{\mathbf{q}}. \quad (6)$$

This equation is also known as *second-order differential kinematics*.

Singularities

A robot configuration $\mathbf{q}$ is *singular* if the task Jacobian matrix is rank-deficient at it. Considering the role of $\mathbf{J}_t$ in (2) and (6), it is easy to realize

that at a singular configuration, it is impossible to generate end-effector task velocities or accelerations in certain directions. Further insight can be gained by looking at (5), which indicates that a singularity may be due to a loss of rank of the transformation matrix T and/or of the geometric Jacobian matrix J .

Rank deficiencies of T are only related to the mathematical relationship between v_N and $t, \dot{t}$; for this reason, a configuration at which T is singular is referred to as a *representation singularity*. A representation singularity is not directly related to the true motion capabilities of the manipulator structure, which can be instead inferred by the analysis of the geometric Jacobian matrix. Rank deficiencies of J are in fact related to loss of mobility of the manipulator end effector; indeed, end-effector velocities exist in this case that are unfeasible for any velocity commanded at the joints. A configuration at which J is singular is referred to as a *kinematic singularity*.

Since redundancy resolution methods involve the inversion of the task differential kinematics (2) and (6), the handling of singularities through proper treatment of the Jacobian matrix is very important. However, due to space limitations, this topic is out of the scope of this article, and in the following we will assume that the Jacobian matrices at issue are all full rank.

Null-Space Velocities

With a full-rank task Jacobian, at each configuration, a $N - M$ dimensional null space of J_t exists made of the set of joint-space velocities that yield zero task velocity; these are thus called *null-space velocities* in short.

Remarkably, the components of $\dot{q}$ in the null space of J_t produce a change in the configuration of the manipulator without affecting its task velocity. This can be exploited to achieve additional goals – like obstacle or singularity avoidance – in addition to the realization of a desired task motion and constitutes the core of redundancy resolution approaches.

Inverse Differential Kinematics

The inverse kinematics problem can be solved by inverting the direct kinematics equation (1),

the first-order differential kinematics (2) or the second-order differential kinematics (6). With a time-varying desired task reference, it is convenient to solve the differential kinematic relationships because these represent linear equations with the task Jacobian as the coefficient matrix.

For a kinematically redundant manipulator, the general solution of (2) or (6) can be expressed by resorting to the pseudoinverse $J_t^\dagger$ of the task Jacobian matrix (Whitney 1969).

The general solution of (2) can be written as

$$\dot{q} = J_t^\dagger(q) \dot{t} + N_{J_t}(q) \dot{q}_0, \quad (7)$$

where

$$N_{J_t}(q) = I - J_t^\dagger(q) J_t(q)$$

is an orthogonal projection matrix into the null space of J_t , and $\dot{q}_0$ is an arbitrary joint-space velocity; the second part of the solution is therefore a null-space velocity. The particular solution obtained by setting $\dot{q}_0 = \mathbf{0}$ in (7) is known as the *pseudoinverse solution*.

As for the second-order kinematics (6), its solution can be expressed in the general form

$$\ddot{q} = J_t^\dagger(q)(\ddot{t} - \dot{J}_t(q, \dot{q})\dot{q}) + N_{J_t}(q) \ddot{q}_0, \quad (8)$$

where $\ddot{q}_0$ is an arbitrary joint-space acceleration.

In summary, for a kinematically redundant manipulator, the inverse kinematics problem admits an infinite number of solutions, so that a methodology to select one of them is needed.

Redundancy Resolution via Optimization

An approach to redundancy resolution is based on the optimization of suitable performance criteria.

Performance Criteria

The availability of redundant degrees of freedom can be used to improve the value of performance criteria during the motion. These criteria may depend on the robot joint configuration only or involve also velocities and/or accelerations.

The most frequently considered performance objective for trajectory tracking tasks is singularity avoidance. In fact, singularities lead to decreased mobility, and adding kinematic redundancy allows to reduce the extension of the workspace region where the manipulator is necessarily at a singular configuration (*unavoidable* singularities Baillieul et al. 1984). Possible performance criteria to drive the manipulator motion out of avoidable singularities are configuration-dependent functions that characterize the distance from singular configurations, i.e., the manipulability measure, the condition number, and the smallest singular value of $\mathbf{J}_t$.

Since kinematic inversion produces very high joint velocities in the vicinity of singular configurations, a conceptually different possibility is to minimize the norm of the joint velocity generated by the redundancy resolution scheme.

Redundancy can be also used to keep a robot away from undesired regions of the joint space or of the task space. For example, it might be desired that a manipulator avoids reaching mechanical joint limits (Liégeois 1977). Another interesting application is obstacle avoidance, which can be enforced by minimizing suitable artificial potential functions defined on the basis of the image of the obstacle region in the configuration space.

Many other performance criteria can be found in the literature.

Local Optimization

Equation (7) provides least-squares solutions to the end-effector task constraint (2), so that it minimizes $\|\dot{\mathbf{t}} - \mathbf{J}\dot{\mathbf{q}}\|$.

The simplest form of local optimization is represented by the pseudoinverse solution that provides the joint velocity with the minimum norm among those which realize the task constraint. Clearly, the joint movement generated by this locally optimal solution does not provide global velocity minimization along the entire manipulator motion; therefore, singularity avoidance is not guaranteed (Baillieul et al. 1984).

In terms of the inverse differential kinematics problem, the least-squares property may quantify the accuracy of the end-effector task realization,

while the minimum norm property may be relevant for the feasibility of the joint-space velocities.

Another possibility is to use the general solution (7), choosing $\dot{\mathbf{q}}_0$ as

$$\dot{\mathbf{q}}_0 = -k_H \nabla H(\mathbf{q}), \quad (9)$$

where k_H is a scalar stepsize and $\nabla H(\mathbf{q})$ denotes the gradient of a scalar configuration-dependent performance criterion H which is desired to minimize (Liégeois 1977).

As for the second-order solution (8), choosing $\ddot{\mathbf{q}}_0 = \mathbf{0}$ gives the minimum norm acceleration solution.

Global Optimization

Local optimization algorithms can lead to unsatisfactory performance over long-duration tasks. It is therefore natural to consider the possibility of selecting $\dot{\mathbf{q}}_0$ in (7) so as to minimize integral criteria of the form

$$\int_{t_i}^{t_f} H(\mathbf{q}) dt$$

defined over the whole duration of the task. Unfortunately, the solution of these problems (naturally formulated within the Calculus of Variations framework) may not exist and does not admit a closed form in general. One way to make the problem solvable is to use an integral criterion in quadratic form in the joint velocities or accelerations. However, this is more easily done at the second-order kinematic level (see section “[Second-Order Redundancy Resolution](#)”).

Redundancy Resolution via Task Augmentation

Another approach to redundancy resolution consists in augmenting the task vector so as to tackle additional objectives expressed as constraints.

Extended Jacobian

The extended Jacobian technique (Baillieul 1985), enforces an appropriate number of functional constraints to be fulfilled along with the original end-effector task.

Given an objective function $g(\mathbf{q})$, if $\mathbf{J}_t$ has full rank, a set of $N - M$ independent constraints can be obtained from the equation

$$\left. \frac{\partial g(\mathbf{q})}{\partial \mathbf{q}} \right|_{\mathbf{q}=\hat{\mathbf{q}}} N \mathbf{J}_t(\hat{\mathbf{q}}) = \mathbf{0}^T,$$

where $\hat{\mathbf{q}}$ is the current joint configuration such that the function $g(\mathbf{q})$ is at an extreme; these $N - M$ independent constraints can be written in vector form as

$$\mathbf{h}(\hat{\mathbf{q}}) = \mathbf{0}.$$

For a motion that tracks a trajectory $\mathbf{t}(t)$ by keeping $g(\mathbf{q})$ extremized at each time, it is

$$\begin{bmatrix} \mathbf{t}(t) \\ 0 \end{bmatrix} = \begin{bmatrix} \mathbf{k}_t(\mathbf{q}(t)) \\ \mathbf{h}(\mathbf{q}(t)) \end{bmatrix},$$

that, similarly to (1) and (2), leads to define an *extended Jacobian* matrix as

$$\mathbf{J}_{\text{ext}}(\mathbf{q}) = \begin{bmatrix} \mathbf{J}_t(\mathbf{q}) \\ \frac{\partial \mathbf{h}(\mathbf{q})}{\partial \mathbf{q}} \end{bmatrix}.$$

Therefore, if the initial joint configuration extremizes $g(\mathbf{q})$ and provided that $\mathbf{J}_{\text{ext}}$ does not become singular, the time integral of the inverse mapping

$$\dot{\mathbf{q}} = \mathbf{J}_{\text{ext}}^{-1}(\mathbf{q}) \begin{bmatrix} \dot{\mathbf{t}} \\ 0 \end{bmatrix} \quad (10)$$

tracks the assigned end-effector trajectory $\mathbf{t}(t)$ propagating joint configurations that extremize $g(\mathbf{q})$.

The extended Jacobian method has a major advantage over the pseudoinverse solution in that it is *cyclic*, i.e., it generates repetitive joint motion from a repetitive task motion. Moreover, solution (10) can be made equivalent to (7) via suitable choice of the vector $\dot{\mathbf{q}}_0$ (Baillieul 1985).

Augmented Jacobian

The task-space augmentation approach is based on the direct definition of a constraint task to be fulfilled along with the end-effector task (Sciavicco and Siciliano 1988).

In detail, let $\mathbf{t}_c$ collect P variables that describe the additional tasks to be fulfilled besides the end-effector task $\mathbf{t}$. In the general case, it is $P \leq N - M$ although full redundancy exploitation suggests to consider exactly $P = N - M$.

The relation between the joint-space and the *constraint-task* coordinates can be considered as a direct kinematics equation

$$\mathbf{t}_c = \mathbf{k}_c(\mathbf{q}),$$

where $\mathbf{k}_c$ is a continuous nonlinear vector function. At this point, an *augmented task* can be defined by stacking the end-effector task with the constraint task as

$$\mathbf{t}_a = \begin{bmatrix} \mathbf{t} \\ \mathbf{t}_c \end{bmatrix} = \begin{bmatrix} \mathbf{k}_t(\mathbf{q}) \\ \mathbf{k}_c(\mathbf{q}) \end{bmatrix}.$$

According to this definition, finding a joint configuration $\mathbf{q}$ that brings $\mathbf{t}_a$ at some desired value means to satisfy both the end-effector and the constraint task at the same time.

A solution to this problem can be found at the differential level by inverting the mapping

$$\dot{\mathbf{t}}_a = \mathbf{J}_a(\mathbf{q}) \dot{\mathbf{q}} \quad (11)$$

where the matrix

$$\mathbf{J}_a(\mathbf{q}) = \begin{bmatrix} \mathbf{J}_t(\mathbf{q}) \\ \mathbf{J}_c(\mathbf{q}) \end{bmatrix}$$

is termed *augmented Jacobian* and $\mathbf{J}_c(\mathbf{q}) = \partial \mathbf{k}_c / \partial \mathbf{q}$ is the $P \times N$ *constraint-task Jacobian* matrix.

A particular choice for the constraint-task vector is $\mathbf{t}_c = \mathbf{h}(\mathbf{q})$, with $\mathbf{h}$ defined as explained in section “[Extended Jacobian](#)” that allows the augmented Jacobian method to embed the extended Jacobian one.

Algorithmic Singularities

The specification of additional goals besides tracking the end-effector task raises the possibility that configurations exist at which the augmented kinematics problem is singular, while the sole end-effector task kinematics is not; these configurations are termed *algorithmic singularities* (Baillieul 1985). With reference to the velocity mappings (10) and (11), an algorithmically singular configuration is one at which the extended and the augmented Jacobians, respectively, are singular while $\mathbf{J}_t$ is full rank.

Remarkably, algorithmic singularities arise from the way in which the constraint task conflicts with the end-effector task and is not a problem of the specific inverse kinematic technique (Baillieul 1985). This is easily understandable in simple situations such as that of a desired trajectory passing through an obstacle; either the trajectory is tracked or the obstacle is avoided, so that both tasks cannot be achieved together. If the origin of the conflict between the two tasks has a clear meaning, the algorithmic singularity may be avoided by keenly specifying the constraint task case-by-case; otherwise, analytical tools must be adopted.

Task Priority

Conflicts between the end-effector task and the constraint task are handled in the framework of the task-priority strategy by suitably assigning an order of priority to the given tasks and then satisfying the lower-priority task only in the null space of the higher-priority task (Maciejewski and Klein 1985; Nakamura et al. 1987). The idea is that, when an exact solution does not exist, the reconstruction error should only affect the lower-priority task.

With reference to solution (7), the task-priority method consists in computing $\dot{\mathbf{q}}_0$ so as to suitably achieve the P -dimensional constraint-task velocity $\dot{\mathbf{i}}_c$. Remarkably, the projection of $\dot{\mathbf{q}}_0$ onto the null space of $\mathbf{J}_t$ ensures lower priority of the constraint task with respect to the end-effector task since it results in a null-space velocity.

Consistently with the defined order of priority between the two tasks, a reasonable choice is then to guarantee exact tracking of the

primary-task velocity while minimizing the constraint-task velocity reconstruction error $\dot{\mathbf{i}}_c - \mathbf{J}_c \dot{\mathbf{q}}$; this gives (Maciejewski and Klein 1985)

$$\begin{aligned} \dot{\mathbf{q}} = & \mathbf{J}_t^\dagger(\mathbf{q})\dot{\mathbf{i}} \\ & + (\mathbf{J}_c(\mathbf{q})\mathbf{N}_{\mathbf{J}_t}(\mathbf{q}))^\dagger (\dot{\mathbf{i}}_c - \mathbf{J}_c(\mathbf{q})\mathbf{J}_t^\dagger(\mathbf{q})\dot{\mathbf{i}}). \end{aligned} \quad (12)$$

It can be recognized that the problem of algorithmic singularities still remains; in fact, the matrix $\mathbf{J}_c \cdot \mathbf{N}_{\mathbf{J}_t}$ may lose rank with full-rank $\mathbf{J}_t$ and $\mathbf{J}_c$. However, differently from the task-space augmentation approach, correct primary-task solutions are expected as long as the sole primary-task Jacobian matrix is full rank. On the other hand, out of the algorithmic singularities, the task-priority strategy gives the same solution as the task-space augmentation approach; this implies that close to an algorithmic singularity, the solution becomes ill-conditioned and large joint velocities may result.

Another approach is to relax minimization of the secondary-task velocity reconstruction constraint and simply pursue tracking of the components of $\mathbf{J}_c^\dagger \dot{\mathbf{i}}_c$ that do not conflict with the primary task (Chiaverini 1997), namely:

$$\dot{\mathbf{q}} = \mathbf{J}_t^\dagger(\mathbf{q})\dot{\mathbf{i}} + \mathbf{N}_{\mathbf{J}_t}(\mathbf{q})\mathbf{J}_c^\dagger(\mathbf{q})\dot{\mathbf{i}}_c. \quad (13)$$

A nice property of solution (13) is that algorithmic singularities are decoupled from the singularities of $\mathbf{J}_c$.

Second-Order Redundancy Resolution

Redundancy resolution at the acceleration level allows the consideration of dynamic performance along the manipulator motion. Moreover, the obtained acceleration profiles (together with the corresponding positions and velocities) can be directly used as reference signals of task-space dynamic controllers.

The simplest scheme operating at the acceleration level is represented by (8) with $\ddot{\mathbf{q}} = \mathbf{0}$. Similar to the velocity-level pseudoinverse solution,

the joint motion generated by this locally optimal solution does not result in global acceleration minimization. Remarkably, provided that the appropriate boundary conditions are satisfied, this solution leads to the minimization of the integral of $\dot{\mathbf{q}}^T \dot{\mathbf{q}}$ (Kazerounian and Wang 1988).

More flexibility in the choice of performance criteria is obviously obtained by considering the full second-order solution (8). Let the manipulator dynamic model be expressed as

$$\boldsymbol{\tau} = \mathbf{H}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) + \boldsymbol{\tau}_g(\mathbf{q}),$$

where $\boldsymbol{\tau}$ is the vector of actuator torques, $\mathbf{H}$ is the manipulator inertia matrix, $\mathbf{c}$ is the vector of centrifugal/Coriolis terms, and $\boldsymbol{\tau}_g$ is the gravitational torque vector. Choosing the null-space acceleration in (8) as

$$\begin{aligned} \ddot{\mathbf{q}}_0 = & -(\mathbf{H}(\mathbf{q})\mathbf{N}_{J_t}(\mathbf{q}))^\dagger \\ & \cdot (\mathbf{H}(\mathbf{q})\mathbf{J}_t^\dagger(\mathbf{q})(\ddot{\mathbf{t}} - \dot{\mathbf{J}}_t(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}}) \\ & + \mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) + \boldsymbol{\tau}_g(\mathbf{q})) \end{aligned}$$

leads to the local minimization of the actuator torque norm $\boldsymbol{\tau}^T \boldsymbol{\tau}$ (Hollerbach and Suh 1987).

Another interesting inverse solution, which minimizes the integral of the manipulator kinetic energy, is the following (Kazerounian and Wang 1988)

$$\begin{aligned} \ddot{\mathbf{q}} = & \mathbf{J}_{t,H}^\dagger(\mathbf{q})(\ddot{\mathbf{t}} - \dot{\mathbf{J}}_t(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}}) \\ & + (\mathbf{I} - \mathbf{J}_{t,H}^\dagger(\mathbf{q})\mathbf{J}_t(\mathbf{q}))\mathbf{H}^{-1}(\mathbf{q})\mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}), \end{aligned}$$

where the *inertia-weighted task Jacobian pseudoinverse* can be computed as

$$\mathbf{J}_{t,H}^\dagger(\mathbf{q}) = \mathbf{H}^{-1}(\mathbf{q})\mathbf{J}_t^T(\mathbf{q})\left(\mathbf{J}_t(\mathbf{q})\mathbf{H}^{-1}(\mathbf{q})\mathbf{J}_t^T(\mathbf{q})\right)^{-1}.$$

Once again, the correct boundary conditions must be used.

Summary and Future Directions

To discuss kinematic redundancy, the concept of task-oriented kinematics has been first recalled with the basic methods for its inversion at the velocity and acceleration level. Next, different methods to solve kinematic redundancy at the velocity level have been arranged in two main categories, namely, those based on the optimization of suitable performance criteria and those relying on the augmentation of the task space. Finally, redundancy resolution methods at the acceleration level have been considered in order to take into account dynamics issues, e.g., torque or kinetic energy minimization.

Besides the classical linear algebra methods and optimization tools still ever under investigation, new methodological approaches to redundancy resolution recently include learning algorithms (Rolf et al. 2010) and soft computing techniques (Liu and Li 2006). Active fields of new applications are in sensorial redundancy for data fusion (Luo and Chang 2012) and in systems (like the one in Fig. 6) with a large number of degrees of freedom, namely, hyperredundant robots (Salviati et al. 2009), humanoids (Kanoun and Laumond 2010), and multirobot systems (Antonelli et al. 2010).

Recommended Reading

Because of space and scope limitations, in drawing an overview of such a mature and well-developed topic, there are a number of techniques and details that go neglected in any case; a slightly more extensive treatment of kinematic redundancy, including a touch on singularity robustness, cyclicity, and hyperredundant manipulators with related first-reading bibliography, can be found in Chiaverini et al. (2008, 2016). Other major issues of interest that could not be covered here are in the use of kinematic redundancy for fault tolerance, for improved grasping and for motion/force control (see, e.g., (Roberts et al. 2008; Ben-Gharbia et al. 2013; Prats et al. 2011; Khatib 1990; Ficuciello et al. 2015), respectively).

Regulation and Tracking of Nonlinear Systems

Lorenzo Marconi

C.A.SY. - DEI, University of Bologna, Bologna, Italy

Abstract

A classical problem in control theory is the design of feedback laws such that the effect of exogenous inputs on selected output variables is asymptotically rejected. This includes problems of asymptotic tracking and disturbance rejection. In this entry, the fundamentals of the theory are presented, as well as constructive procedures for the design of a controller, which embeds an “internal model” of the generator of the exogenous inputs. Current and future research directions are also discussed.

Keywords

Nonlinear output regulation · Robust control · Stabilization of nonlinear systems · Tracking

Introduction

The problem of controlling a dynamical systems in such way that a “regulated” output tracks reference signals or rejects exogenous disturbances is ubiquitous in control theory. Among various possible different approaches to the solution of this problem, in this entry we present the so-called theory of nonlinear output regulation. A distinctive feature of this theory is that reference/disturbance signals to be tracked/rejected are thought of as unknown functions of time, which belong to the set of all trajectories generated by an autonomous nonlinear system (the so-called *exosystem*). Fundamental in this setting is the concept of *internal model*, developed in the early 1970s for linear systems by Francis and Wonham (1976) and subsequently extended, beginning with the work (Isidori and Byrnes

1990), to the case nonlinear systems. Since these early contributions, nonlinear output regulation has been an active research domain, in which constant improvements have brought the theory to a stage of full maturity. In this entry we introduce the fundamental principles of the nonlinear output regulation theory and the associated design tools. The entry ends with an overview of actual research trends and future research directions.

The Generalized Tracking Problem for Nonlinear Systems

We consider the class of time-invariant smooth nonlinear systems described in the form

$$\begin{aligned}\dot{x} &= f(w, x, u) \\ e &= h(w, x) \\ y &= k(w, x)\end{aligned}\tag{1}$$

in which $x \in \mathbb{R}^n$ is the state, $u \in \mathbb{R}^m$ is the control input, $y \in \mathbb{R}^q$ is the measured output, and $e \in \mathbb{R}^p$ is the regulation *error*. The input $w \in \mathbb{R}^s$ models exogenous signals that might represent references to be tracked, exogenous disturbances to be rejected, or also parametric uncertainties. In this framework the problem is to design a controller of the form

$$\begin{aligned}\dot{\xi} &= \varphi(\xi, y) & \xi &\in \mathbb{R}^v \\ u &= \gamma(\xi, y)\end{aligned}\tag{2}$$

such that the associated closed-loop system (1)–(2) has bounded trajectories $(x(t), \xi(t))$ and the resulting error $e(t) = h(w(t), x(t))$ is asymptotically vanishing, i.e., $\lim_{t \rightarrow \infty} e(t) = 0$. The previous framework encompasses several standard control problems, such as the problem in which a system of the form $\dot{x} = f(x, u)$, with measured output $y = k(x)$ and regulated output $y_r = h_r(x)$, must be controlled in such a way that $y_r(t)$ asymptotically tracks a reference signal $y^*(t)$. This is the case, in fact, if we set $w(t) = y^*(t)$, define $e = h(w, x) = w - h_r(x)$, and drop the dependence from w in the functions $f(\cdot)$ and $k(\cdot)$ in (1). Similarly, the previous framework lends itself to capture a scenario of disturbance suppression, in which, in a system of

the form $\dot{x} = f(d, x, u)$, with measured output $y = k(x)$ and regulated output $y_r = h(x)$, the effect of a disturbance $d(t)$ on the regulated output $y_r(t)$ must be asymptotically rejected. This is the case if we set $w(t) = d(t)$ and drop the dependence on w in $h(\cdot)$ and $k(\cdot)$ in (1). Similarly, by letting $h(x) = x$ and interpreting the variable w as parametric uncertainty, the previous setting captures the problem of robust output feedback stabilization, at the origin, of an uncertain system of the form $\dot{x} = f(w, x, u)$ with measured output $y = k(w, x)$. Of course, the general case of tracking reference signals in presence of exogenous disturbances can be cast in a similar manner.

The ability of solving the problem in question strongly depends on the amount of knowledge one assumes about the exogenous variable w in the design of the controller (2). Among the different options available, in this entry we present the so-called theory of output regulation, in which the exogenous variable is assumed to be an *unknown member* of a *known family* of functions of time. Specifically, it is assumed that $w(t)$ is an unspecified member of the set of all trajectories generated by an autonomous nonlinear system of the form

$$\dot{w} = s(w) \quad (3)$$

as its initial condition $w(0)$ ranges on a prescribed set $W \subset \mathbb{R}^s$. In this framework, system (3), usually referred to as the “exosystem,” is assumed to be known and its knowledge potentially exploitable in the design of (2). The specific “member” $w(t)$ of the family, however, is unspecified as the initial condition $w(0)$ is not known. The fact of regarding $w(t)$ as unknown member of a known family seems to be the right trade-off between the favorable but unrealistic situation in which $w(t)$ is assumed to be perfectly known and the opposite realistic but conservative situation in which $w(t)$ is regarded as a totally unknown signal. An elementary, and yet meaningful, example is given by the case in which $w(t)$ belongs to the family of periodic functions of time with an unspecified frequency, phase, and amplitude. In this case the exosystem (3) is a *nonlinear* system

of the form ($w \in \mathbb{R}^3$)

$$\dot{w}_1 = w_2 \quad \dot{w}_2 = -w_3^2 w_1 \quad \dot{w}_3 = 0.$$

Solutions of the previous system, in fact, are periodic functions, with frequency $w_3(t) \equiv w_3(0)$ and amplitude and phase depending on the specific initial condition $(w_1(0), w_2(0))$. Other situations, such as exosystems modeling nonlinear oscillators, can be dealt with in a similar fashion.

In the previous context, the problem of output regulation can be formally cast as follows. Let $X \subset \mathbb{R}^n$ be a set of initial conditions for (1). Then, the problem consists in finding a controller of the form (2), with initial conditions in a set $\mathcal{E} \subset \mathbb{R}^v$, such that the trajectories of the closed-loop system (1)–(2) augmented with (3), originating from an initial condition $(w(0), x(0), \xi(0)) \in W \times X \times \mathcal{E}$, are bounded and $\lim_{t \rightarrow \infty} e(t) = 0$ *uniformly* in the initial conditions (The property of “uniformity” is relevant in the context of output regulation. It reflects the requirement that the time needed for the error $e(t)$ to reach an ϵ -neighborhood of the origin only depends on the set $W \times X \times \mathcal{E}$, where the initial conditions are supposed to range, and on ϵ but not on the particular value of the initial condition within $W \times X \times \mathcal{E}$.) Depending on the assumptions on the set X where the initial conditions of the plant are assumed to range, the problem is further classified in *semiglobal output regulation*, if the set X is a known *compact* but otherwise arbitrary set of $\mathbb{R}^n$, or *global output regulation* if $X = \mathbb{R}^n$.

Output Regulation Principles

Steady State for Nonlinear Systems and Internal Model Principle

Since the objective is to design the controller such that the effect of the exogenous variable is *asymptotically* rejected by the regulation error, it is apparent that any approach to the solution of the problem of output regulation must be

necessarily grounded on a precise characterization of the notion of “steady state” for a nonlinear system. As it is the case for the familiar version of this concept in linear systems theory, a notion of “steady state,” for the system consisting of (1)–(3), should be able to capture the “limiting behavior” – if any – that such system asymptotically approaches when the “transient behavior,” due to the effect of specific initial conditions of plant and controller, fades out and a “persistent behavior,” induced only by the specific exogenous input, emerges. In this respect, the mathematical tool that has been shown to be at the core of a rigorous notion of steady state for nonlinear systems is the one of ω -limit set of a set. We refer the reader to Hale et al. (2002) for a definition of this notion and to Byrnes and Isidori (2003) for a description of its use in the characterization of the steady-state behavior of a nonlinear system. In this entry, we simply observe that if the trajectories of the system (3)–(1)–(2) that originate from the set of initial conditions $W \times X \times \mathcal{E}$ are bounded (which, in turn, is one of the requirements of the problem in question), then there exists a compact set $\mathcal{A} \subset \mathbb{R}^s \times \mathbb{R}^n \times \mathbb{R}^v$, which is precisely the ω -limit set of the set $W \times X \times \mathcal{E}$ under the dynamics of (3)–(1)–(2), that is *invariant* for the closed-loop system and that *uniformly* attracts its trajectories. The set $\mathcal{A}$ is usually referred to as *steady-state locus*, while the restriction of the closed-loop dynamics to the set $\mathcal{A}$ are the *steady-state dynamics* of the closed-loop system. The latter characterize the “limiting behavior” of the system towards which all the closed-loop trajectories converge to. Unlike the case of linear systems, though, in a nonlinear context we cannot expect, in general, that the steady-state behavior is only governed by the exogenous w , namely, that the asymptotic behavior of the closed-loop system is totally independent of the initial conditions of the plant and of the regulator. Assuming that the set W is compact and invariant for (3), it can be proven (see Isidori and Byrnes 2008) that the set $\mathcal{A}$ is the graph of a *set-valued* map defined on W , namely, that there exists a map $\sigma : W \rightarrow \mathbb{R}^n \times \mathbb{R}^v$, which is set-valued in general, such that

$$\mathcal{A} = \{(w, x, \xi) \in W \times \mathbb{R}^n \times \mathbb{R}^v : (x, \xi) \in \sigma(w)\}.$$

Clearly the steady-state locus and the associated steady-state dynamics of the closed-loop system depend on the design of the controller (2). The role of the latter is not only to enforce the existence of a steady state, which is equivalent to enforce bounded closed-loop trajectories, but also to guarantee that the error converges asymptotically to zero uniformly in the initial conditions. In this respect, by bearing in mind the asymptotic properties of the set $\mathcal{A}$, it can be seen that a sufficient condition under which a regulator of the form (2) solves the problem of output regulation is that the steady-state locus is “shaped” in such a way that the regulation error is zero on it, namely,

$$\mathcal{A} \subset \{(w, x, \xi) : h(w, x) = 0\}. \quad (4)$$

In fact, it can be proved that condition (4) is not only sufficient but also necessary (see Byrnes and Isidori 2003) as a consequence of the requirement that the error converges to zero uniformly in the initial conditions. That is, any regulator that solves the problem in question necessarily enforces a steady state such that the steady-state locus fulfills (4).

In view of the previous considerations, a crucial property required to any regulator is to induce a steady-state locus $\mathcal{A}$ fulfilling (4). This key feature can be further elaborated by highlighting two necessary conditions, involving separately the plant and the regulator, leading to the notions of *regulator equations* and *internal model property*. To this purpose, consider the simplified, yet relevant, case in which the map $\sigma(\cdot)$ is single-valued and smooth, and let $\pi(w)$ and $\tau(w)$ be the two components of $\sigma(w)$ associated to x and ξ , respectively. By letting

$$c(w) = \gamma(\tau(w), k(w, \pi(w))) \quad (5)$$

it is immediately realized that the fact that $\mathcal{A}$ is invariant for (1)–(3) implies that the functions $\pi(\cdot)$ and $\tau(\cdot)$ necessarily fulfill

$$\frac{\partial \pi(w)}{\partial w} s(w) = f(w, \pi(w), c(w)) \quad (6)$$

and

$$\frac{\partial \tau(w)}{\partial w} s(w) = \varphi(\tau(w), k(w, \pi(w))) \quad (7)$$

for all $w \in W$. Furthermore, the fact that e must be zero on $\mathcal{A}$ (see (4)) implies that necessarily

$$h(w, \pi(w)) = 0 \quad (8)$$

for all $w \in W$. Equations (6) and (8), interpreted as equations in the unknown $\pi(w)$ and $c(w)$, involve only the regulated plant (1) and are known as *regulator equations* (see Isidori and Byrnes 1990; Isidori 1995). The functions $c(w(t))$ and $\pi(w(t))$, with $w(t)$ solution of (3), represent, respectively, the desired steady-state control input and state towards which the actual control input u and state x of (1) should converge in order to have the regulation goal fulfilled. On the other hand, Eqs. (5) and (7), interpreted as equations in the unknown $\tau(w)$, point out the so-called internal model property required to any regulator solving the output regulation problem, that is, the ability of the regulator to reproduce the ideal steady-state input $c(w(t))$, for all possible $w(t)$ solution of (3), once it is driven by the measured output of the plant in the ideal steady state (namely, by the function $k(w(t), \pi(w(t)))$). In fact, this property can be achieved by incorporating in the controller an appropriate “internal model” of the exogenous dynamics (3).

Regulator Design

As emphasized in the previous discussion, the design of the regulator involves the fulfillment of two crucial properties. The first is the internal model property, namely, the ability of generating, by means of the regulator outputs, all possible “feedforward inputs” which force an identically zero regulation error and, in turn, to guarantee the existence of an invariant steady-state set on which the error is identically zero. The second property asks that such a steady-state set is asymptotically stable for the

closed-loop system with a domain of attraction including the set of initial conditions. A systematic design procedure of regulators simultaneously fulfilling the previous two properties can be found under sufficient conditions that essentially restrict the class of regulated plants (1). In particular, in the following, we consider the class of single input-single output systems that are affine in the input u , with a measurable error variable (i.e., $e = y$) and that after an appropriate change of coordinates can be written in the form

$$\begin{aligned} \dot{z} &= f_z(w, z, e) & z &\in \mathbb{R}^{n-1} \\ \dot{e} &= a(w, z, e) + b(w, z, e)u & e, u &\in \mathbb{R} \end{aligned} \quad (9)$$

with $f_z(\cdot, \cdot, \cdot)$, $a(\cdot, \cdot, \cdot)$, and $b(\cdot, \cdot, \cdot)$ smooth functions with $b(w, z, e) \neq 0$ for all (w, z, e) . Systems of this kind possess a well-defined unitary relative degree (The restriction to systems with unitary relative degree is just made for sake of simplicity. Higher relative degree can be equally dealt with, Isidori (1995).) between the input u and the output e , and the Eqs. (9) are said to be in *normal form* (see Isidori 1995, 2013). In these coordinates an easy calculation shows that the solution of the regulator Eqs. (6) and (8) takes the form $\pi(w) = (\pi_z(w), 0)$, where $\pi_z(\cdot) : W \rightarrow \mathbb{R}^{n-1}$ is a solution of

$$\frac{\partial \pi_z(w)}{\partial w} s(w) = f_z(w, \pi_z(w), 0),$$

and

$$c(w) = -\frac{a(w, \pi_z(w), 0)}{b(w, \pi_z(w), 0)}.$$

In addition, we further restrict the class of systems by asking for a minimum-phase property (Isidori 1995, 2013). In the present context, the property in question amounts to asking that the set $\mathcal{B} = \{(w, z) \in W \times \mathbb{R}^{n-1} : z = \pi_z(w)\}$ is *asymptotically stable* for the system

$$\begin{aligned} \dot{w} &= s(w) \\ \dot{z} &= f_z(w, z, 0) \end{aligned}$$

with a domain of attraction containing $W \times Z$, with Z the set where the initial condition of z is expected to range.

Existence of the relative degree and the property of minimum-phase are all what is needed to design a regulator. The regulator takes the form

$$\begin{aligned}\dot{\xi} &= F\xi + G(\gamma(\xi) + \kappa(e)) \quad \xi \in \mathbb{R}^v \\ u &= \gamma(\xi) + \kappa(e)\end{aligned}\quad (10)$$

in which (F, G) is a controllable pair and $\gamma(\cdot)$ and $\kappa(\cdot)$ are real-valued functions to be properly designed. In particular, it can be shown (see Marconi et al. 2007) that if v , the dimension of the regulator is taken sufficiently large relative to the dimension of w (specifically, $v \geq 2s + 2$) and if F is any matrix whose eigenvalues have negative real part, there exist a continuously differentiable function $\tau(\cdot)$ and a continuous function $\gamma(\cdot)$ such that

$$\begin{aligned}\frac{\partial \tau(w)}{\partial w} s(w) &= F\tau(w) + Gc(w) \\ c(w) &= \gamma(\tau(w))\end{aligned}\quad (11)$$

for all $w \in W$. This being the case, it is seen that the regulator (10) fulfills conditions (5)–(7) and therefore has the internal model property, regardless of how $\kappa(\cdot)$ is chosen, provided that $\kappa(0) = 0$. In particular, in the closed-loop system (3), (9), and (10), the invariant set $\mathcal{A} = \{(w, z, e, \xi) \in W \times \mathbb{R}^{n-1} \times \mathbb{R} \times \mathbb{R}^v : z = \pi_z(w), e = 0, \xi = \tau(w)\}$ fulfills (4) regardless of how $\kappa(\cdot)$ is chosen. The function $\kappa(\cdot)$ is a degree of freedom that can be chosen to make the steady-state set $\mathcal{A}$ asymptotically stable. In this respect the minimum-phase assumption and the fact that F is a Hurwitz matrix play a role. In fact, the closed-loop system (3), (9), and (10), interpreted as a system with state (w, z, e) , input $\kappa(\cdot)$, and output e , have relative degree one and it is minimum-phase. This fact makes it possible to use standard high-gain arguments to show that there exists a function $\kappa(\cdot)$ such that the set $\mathcal{A}$ is asymptotically stable for the closed-loop systems with a domain of attraction containing any (arbitrarily large) compact set of initial conditions (see Teel and Praly 1995; Marconi et al. 2007).

The delicate part in the procedure illustrated above is the design of the function $\gamma(\cdot)$ that is

required to fulfill (11) for a suitable $\tau(\cdot)$. Exact, although hardly implementable in practice, expressions for the function $\gamma(\cdot)$ can be found in Marconi and Praly (2008). More constructive design procedures can be found at the price of restricting the class of systems and exosystems that can be dealt with. Such procedures require that the autonomous dynamical system with “output” u^*

$$\begin{aligned}\dot{w} &= s(w) \\ u^* &= c(w),\end{aligned}$$

namely, the system characterizing all possible ideal steady-state inputs, is “immersed” into a system exhibiting certain structural properties (Loosely speaking, the autonomous system with output Σ is immersed into the autonomous system with output $\tilde{\Sigma}$ if the set of all possible functions of time generated as outputs of Σ is a subset of the set of all possible functions generated as outputs of $\tilde{\Sigma}$). In this respect a number of alternative solutions have been proposed in literature that differ for the kind of underlying immersion assumption and consequent regulator design procedure. Immersion into a linear known observable system (see Huang and Lin 1994; Khalil 1994; Byrnes et al. 1997; Serrani et al. 2000), immersion into a linear unknown (but linearly parameterized) system (Serrani et al. 2001), immersion into a linear system having a nonlinear output map (Chen and Huang 2004), immersion into a nonlinear system linearizable by output injection (Delli Priscoli 2004), immersion into a system in canonical observability form Byrnes and Isidori (2004), and immersion into a system in a nonlinear adaptive observability form Delli Priscoli et al. (2006a, b) are a few examples of approaches proposed in literature.

Summary and Future Directions

The theory of output regulation for nonlinear systems is an active area of investigation. Research efforts are, in particular, addressed to the problems of weakening the minimum-

phase assumption and of identifying *robust* design procedures, to asymptotically stabilize the steady-state locus, not necessarily based on high-gain principles. Recently, the problem of output regulation for multivariable systems has been also addressed (Isidori and Marconi 2012). In this case a paradigm shift in the design of the regulator and of the stabilizer is expected to deal with the problem in its full generality. Finally, it is worth mentioning that the theory of output regulation and internal model-based design methods are being used for the problem of reaching a consensus between the outputs of a network of nonlinear systems exchanging relative information over a communication graph. In this case it has been proved the necessity of internal model-based regulators (Wieland 2010) and the research activity is now conveyed to identify constructive design strategies for classes of nonlinear systems and network topologies.

Abstract

In this entry, common robotic architectures employed in rehabilitation robotics are presented, focusing on their specific strengths and drawbacks, with examples of commercially available devices for each architecture. The main control strategies currently implemented to promote brain plasticity and functional recovery via robot-aided rehabilitation are illustrated. Finally, current trends and future directions in the field are discussed.

Keywords

Stroke · Robotic architectures · Impedance control

Introduction

Among cardiovascular diseases, stroke is one of the main causes of long-term disability in modern countries. Although statistics suggest that the global incidence of stroke is decreasing, the absolute number of strokes is expected to increase dramatically in few years, leading to 1.5 million European people suffering a stroke each year by 2025 (Béjot et al. 2016). This trend can be associated to the improvement of the quality of life and the consequent increase of life expectation. Such phenomena are gradually shaping our modern society, which is called upon to tackle the issues of population aging and its sustainability. A growing number of people will be at higher risk of developing age-associated chronic diseases, seriously impacting the healthcare system and related services. As

an example, common consequences of a stroke arise as cognitive or physical impairments. In about 85% of the cases, stroke results in muscle weakness affecting one side of the body (hemiparesis), limiting independence of affected people in performing common activities of daily living. Few months after stroke occurs, some conditions might emerge due to immobility, as different expressions of the upper motor neuron syndrome (UMNS). These include modifications of physiological stretch reflex, whose hyper-excitability results in involuntary, spastic muscle contractions. Spasticity of the shoulder girdle muscles occurs in most cases in the hemiplegic arm, forcing to unnatural and painful postures. Starting during acute phases, high-intensity and long-duration physical therapy becomes essential to mitigate the onset of spasticity, relearn motor skills, and maximize functional recovery. Traditional therapy performed in rehabilitation centers consists of one-to-one sessions between patient and therapist, who needs to perform manual mobilization of the affected limb typically for 1 hour, requiring significant physical effort and time.

For this reason, robot-aided rehabilitation has soon emerged as a powerful tool to increase the efficacy of the rehabilitation process, coming in aid of physical therapists for delivering repetitive, measurable, and effective treatments. The general trend of modern clinical rehabilitation favors the employment of a robotic device, provided with sensors able to register a large amount of quantitative data (e.g., range of motion, forces, speed, residual voluntary action), to allow physicians a more objective and repeatable evaluation of the patient's condition. Rehabilitation robotics can lead to disruptive advantages in tackling patient's impairments, reducing the therapists' workload, allowing them to follow more than one patient simultaneously, with the possibility to improve and adapt the therapy based on experimental observations. Although the benefits of robot-aided rehabilitation in terms of recovery of motor functions over traditional physical therapy are debated, the former is gradually introduced by physicians into the standards of care because of the aforementioned advantages.

Robot Architectures

Rehabilitation robots can be classified in four main architectures, based on their physical human-robot interface. On account of their specific strengths and weaknesses, there are no preferred solutions in the state of the art; indeed the choice is strongly dependent on the targeted end users and the need for balancing and prioritizing between power, costs, ease of use, and actual deployment in clinical settings.

Endpoint manipulators were the first to be introduced in the state of the art, by virtue of their low mechanical complexity and ease of setup. They interface with the human limb only at a distal portion, usually by means of a handle (in the case of devices for upper-limb physical rehabilitation), resulting in an intrinsically safe operation. Nevertheless, they lack the possibility to address human joints in a selective manner; thus they are less effective in preventing abnormal compensatory movements occurring often in poststroke patients. The MIT-MANUS (Fig. 1a) is a planar endpoint manipulator, which has been involved in the highest number of clinical trials and the first to underline the importance of engaging and challenging patients with game-like visual feedbacks to guide the user's movements (Krebs et al. 2004). It is currently commercialized by Bionik Laboratories (Toronto, Canada) under the

name of InMotion™, in different configurations for arm, hand, and wrist rehabilitation.

Cable suspensions respond to the needs of reconfigurable, light-weighted robots, where freedom of movement is maximized whereas inertial effects due to the device presence are minimized. Forces or torques are transmitted by means of remotely actuated tendon cables, attached to the user at a single point or at different points around the addressed body segment. The Freebal is endowed with spring mechanisms for weight compensation of the elbow and wrist, which provide constant vertical forces at the sling attachments by means of cable pulleys placed on an overhead fixed beam guide (Stienen et al. 2007). With a similar structure, DIEGO® (Tyromotion, Graz, Austria – Fig. 1b) is a commercially available cable suspension, designed to treat one or both arms via a computer-assisted virtual reality system. Slings attached to the user's arm and/or hand provide active training options for the respective proximal or distal joints or the entire upper extremity, via gravity compensation, enabling treatment of conditions such as hemiparesis, spasticity, or restricted joint mobility.

Powered “rigid” exoskeletons are considered by many researchers as a suitable solution to provide movement assistance in a more physiological

Rehabilitation Robots, Fig. 1 Common architectures for robot-aided rehabilitation: (a) endpoint manipulator MIT-Manus. (Adapted from Krebs et al. 2004); (b) cable suspension DIEGO® (Tyromotion, Austria); (c) Armeo

manner, by acting selectively on each target human joint with the ultimate goal to retain and foster the physiological muscle synergies. In the last decade, they have been witnessed a capillary diffusion across several branches of modern society, as assistive tools in work environments, rehabilitation devices in clinical settings, or power augmentation systems in the military field. The Armeo Power (Nef et al. 2009 – Fig. 1c), and the Lokomat (Colombo et al. 2001 – Fig. 1d) are two powered exoskeletons commercialized by Hocoma (Volketswil, Switzerland), designed for the rehabilitation of the upper and lower limb respectively. They allow highly intensive and repetitive training of limb motor functions in a tridimensional environment, engaging patients with augmented performance feedback exercises. On the one hand, quantitative parameters are extracted to provide patients with visual feedback about their capability of fulfilling the current task, with the aim of increasing their motivation and improving their performance. On the other hand, such parameters are used to evaluate how patients perform during their therapy sessions and adaptively modify the support they receive from the robot. With respect to other robotic architectures, the improved performance in terms of power and precision and the possibility to address specifically each single joint retaining functional muscle synergies come at the expense of a higher mechanical complexity. Indeed, when motion is transmitted, the kinematic chain of the exoskeleton must be able to follow the physiological displacement of the human articulations, which exhibit a certain degree of laxity. Additional passive degrees of freedom (DOF) are usually embedded to realize so-called *self-aligning* kinematic chains, able to cover the residual movements of human joints. If proper alignment between the exoskeleton joint and the addressed articulation is guaranteed, force/torque can be transferred at the collocated human joint without generating residual tangential forces causing pain or discomfort to the user.

Finally, *powered “soft” exoskeletons*, including *exosuits* for the whole body or *exogloves* for the hand, are currently being developed to overcome the main limitations of their

rigid counterpart. Portability, wearability, and lightness are maximized by virtue of their mechanical structure, embedding actuators within clothing-like fabric frames intrinsically adaptable to the addressed body structures. Bioinspired cable transmission systems are used in a tendon-like fashion, with origin and insertion points across the human articulations, which are exploited directly to produce motion similarly to the human muscles and tendons. Soft architectures exhibit very low encumbrance and inertia and inherently solve the problem of joint misalignment. Nevertheless, with respect to rigid exoskeletons, they suffer from narrower bandwidth and lower transmission efficiency, resulting suitable for the rehabilitation of patients with a moderate level of impairment. The Gloreha Sinfonia (*Idrogenet Srl*, Lumezzane, Italy – Fig. 1e) is an example of commercial exoglove designed for hand rehabilitation, able to assist totally or partially the movement of the hand, according to the patient’s residual capabilities (Borboni et al. 2016).

Common Features of Rehabilitation Robots

Common to all rehabilitation robots is their capability to adapt the supplied therapy (i.e., movement assistance) to the end users, thus coping with their different levels of movement capabilities. Adaptation is realized by means of a mix of both hardware and software device capabilities.

From the hardware perspective, a desirable feature of rehabilitation robots is their capability to exhibit – when needed – a minimum-to-null output impedance, thus allowing the implementation of a variety of physical training strategies, with a different level of involvement of the patient in the execution of the movement. Within this framework, the use of compliant actuators, e.g., series elastic actuators (Pratt and Williamson 1995), is becoming a favorable choice to invent and develop innovative rehabilitation robots (Otten et al. 2015; Ercolini et al. 2018). Indeed, hardware compliance is introduced in the robot design to upper limit the inherent robot stiffness

so that the user will always experience a safe and comfortable interaction even in the case of sudden and impulsive movements, such as in the cases of spastic reactions or abnormal muscle activations.

From the viewpoint of the software, the more relevant common feature is the capability of the control system to adapt the assistive action to the different user's residual movement capabilities, along with the progression of the recovery process. All control strategies employed in robot-aided rehabilitation fall within two main categories, namely, "*device-in-charge support*" and "*patient-in-charge support*" strategies (Haarman et al. 2016). The device-in-charge scheme operates by dragging the user's limb to follow a preset trajectory in the working space. The robot delivers completely passive mobilization, by compensating for any deviation from the desired path regardless of the contribution of the user. Usually implemented in the form a position control, where each of the robot joint follows a pre-defined trajectory, this modality of operation is preferred in the early stages of rehabilitation, in which patients exhibit nearly null movement capabilities.

On the contrary, the patient-in-charge scheme includes all situations in which an active interaction between the user and the robot is required. It replicates physician's actions on the user's limb, who initiate the movement and provide assistive forces *as needed*, leaving the patient the control of the task. Patient-in-charge schemes are implemented via force or torque control, enabling the robot either to act as "transparent" to the user without hindering spontaneous movements (zero-torque control) or to provide specific joint torques in aid of the patient. This scheme is particularly suitable at later stages of the rehabilitation process, when patients have regained some motor functions.

Switching between these features can be attained by means of *impedance* or *admittance* control strategies. Mechanical impedance is defined as the relationship between the net force applied to the robot $F(s)$ and the resulting

displacement $X(s)$. For a linear, time-invariant system, the mechanical impedance in the frequency domain has the following formulation (Masia et al. 2018):

$$Z(s) = \frac{F(s)}{X(s)} = Ms^2 + Bs + K, \quad (1)$$

where M , B , and K represent the mass, damping, and stiffness parameters of the coupled system (i.e., robot and human). The admittance is defined as the reciprocal of the impedance. An impedance control strategy is based on the tuning of a desired impedance Z_d , by choosing the desired virtual parameters M_d , B_d , K_d of the coupled system.

A closed-loop impedance control comprises an inner force controller and an outer position controller. For a given desired trajectory $X_d(s)$, the desired force for the actuator is given by:

$$F_d(s) = Z_d(s) [X_d(s) - X(s)]. \quad (2)$$

Thus, the robot can be transparent not to hinder user's movements by tuning its mechanical output impedance to a quasi-zero value. Desired forces for the actuator will be relatively low, even in case of high deviations from the desired path. When impedance is set to high values, the robot becomes stiffer, and its contribution in mobilizing the patient's limb is predominant, i.e., deviations from the desired path are smaller.

For non-backdrivable actuators, or when an accurate force control of the actuator is not practicable (e.g., lacking of joint force sensors), admittance control strategies are preferred. A closed-loop admittance control comprises an inner position controller and an outer torque controller. The desired actuator position $X_d(s)$ is generated based on the net force $F(s)$ applied to the robot and measured by a force sensor located at the robot end effector:

$$X_d(s) = \frac{F(s)}{Z_d(s)}. \quad (3)$$

In many cases, an adaptive law is chosen in order to adjust the value of the impedance within each movement, session, or day of treatment, according to specific performance parameters (Marchal-Crespo and Reinkensmeyer 2009):

$$G_{i+1} = fG_i + ge_i, \quad (4)$$

where i can be the current movement, session, or day, G is the value of the control parameter (e.g., robot stiffness), e is the performance error, and f and g are forgetting and gain factors, respectively. As example, some studies involving the endpoint manipulator MIT-Manus consider four performance measures, calculated based on the ability of the patient to (i) initiate the movement; (ii) move from the starting position to the target; (iii) maintain a linear trajectory toward the target; and (iv) reach the target position (Krebs et al. 2003). Control parameters such as movement time are then adapted with a forgetting factor $f = 1$. For an impedance control, by choosing a forgetting factor between 0 and 1, the robot impedance decreases when the performance error is small, making the rehabilitation exercise more challenging.

Assistive strategies are by far the most common in rehabilitation robotics and has been validated extensively in clinical trials. Nevertheless, according to the method adapted to encourage brain plasticity, other control strategies have been developed, including *challenge-based* algorithms (Marchal-Crespo and Reinkensmeyer 2009). These include all the controllers that operate by resisting user's movements. In their simplest implementation, constant resistive forces can be applied to the affected limb, regardless of the intended movement of the user. In other cases, an error-amplification control strategy can be employed. Opposed to error-cancellation strategies, it creates a divergent force field around the desired movement, in order to enhance kinematic errors and stimulate motor adaptation in performing the task. Resistive strategies can also be implemented by selectively cancelling gravity support to the robot, forcing

the user to contribute to the movement with higher effort.

Summary and Future Directions

Robot-aided rehabilitation is a well-established paradigm in current clinical practice. Robotic architectures for rehabilitation and related control strategies have been developed with a variety of features and the possibility to treat several pathologies and rehabilitate different body segments. A novel trend toward optimization of robot-aided rehabilitation is focused on the creation of robotic gyms, in which several robots are at the disposal of users having different levels of impairments, involving either upper or lower limbs or both. A robotic gym can constitute potentially a cost-effective solution to classic one-to-one therapy, by allowing several patients to perform their rehabilitation sessions at the same time, under the supervision of a single therapist. On the same direction, another cost-effective solution is the deployment of rehabilitation robots in home environment. The patient's home can be transformed into a place where the same rehabilitation treatment can be performed by means of personalized, game-like challenging exercises, guaranteeing a continuum of the rehabilitation process in the medium and long term. For this purpose, virtual reality systems can be employed to broaden the use scenarios, by creating a variety of engaging exercises and real-life tasks, whose difficulty can be graded to the user's capabilities. At the same time, remote monitoring of the patient's performance would allow therapists to keep track of the user's progress and modify the treatment accordingly.

Reinforcement Learning and Adaptive Control

Girish Chowdhary, Girish Joshi, and Aaron Havens
University of Illinois at Urbana Champaign,
Urbana, IL, USA

Abstract

Reinforcement learning (RL) is a machine learning paradigm in which an agent attempts to learn a control policy that can generate the desired sequence of actions for achieving a higher level objective. RL promises to provide a learning mechanism via which autonomous agents can learn to control themselves directly through experience, without requiring manual coding of control policies. Similar to other machine learning paradigms, RL research heavily focuses on end-to-end learning, which in this case is learning of policies directly through experience. Recent successes of RL have shown that agents can learn to decision making and control policies on complex simulations for which it would have been very difficult to manually create control policies. Some examples include chess, go, and more recently complex continuous time-simulated domains. Some pressing issues include sample complexity, robustness, and reliable simulations to the real-world transfer.

Control · Adaptation · Reinforcement learning

Introduction

Reinforcement learning (RL) is a machine learning paradigm in which an agent attempts to learn a control policy that can generate the desired sequence of actions for achieving a higher-level objective. RL promises to provide a learning

mechanism via which autonomous agents can learn to control themselves directly through experience, without requiring manual coding of control policies. Similar to other machine learning paradigms, RL research heavily focuses on end-to-end learning, which in this case is learning of policies directly through experience. Recent successes of RL have shown that agents can learn decision-making and control policies on complex simulations for which it would have been very difficult to manually create control. Some challenges and future directions of work include improving the sample complexity of finding policies, and increasing the robustness of learned policies to noise and dynamic changes.

RL in the Markov Decision Process Framework

A stochastic process $\{s_k\}$ is termed Markovian if the conditional probability of a future event s_{k+1} depends only on the event immediately preceding, and not the entire history of events. In particular, $p(s_{k+1}|s_k) = p(s_{k+1}|s_k, s_{k-1}, s_{k-2}, \dots)$. The Markov decision process (MDP) framework leverages this very key property to lay out a sequential decision-making framework: a Markov decision process (MDP) is a tuple $\langle \mathcal{S}, \mathcal{A}, R, \mathcal{P}, \gamma \rangle$, with state space $\mathcal{S}$, action space $\mathcal{A}$, reward function $r(s, a) \in \mathbb{R}$, transition function $p(s_{k+1}|s_k, a_k) \in \mathcal{P}$, and discount factor $\gamma \in [0, 1)$. The goal of the decision-making agent is to find a sequence of actions a_k such that the reward is maximized. The reward can be sparse and delayed, that is, it is only available at some states, or only available after a sequence of actions are performed. This makes the MDP sequential decision-making problems quite different and rather interesting. As such, the formulation we discuss below assumes that $\gamma < 1$ and is necessary for infinite horizon sequential decision-making problems. In finite horizon problems, such as those studied in Bertsekas et al. (1995) and Bertsekas and Tsitsiklis (1996), γ can take other values.

Given a state s_k , a deterministic non-stationary policy $\pi : \mathcal{S} \rightarrow \mathcal{A}$ that outputs an action $a_k = \pi(s_k)$. The goal of MDP problems is to seek out a policy that leads to maximum reward. To further formulate the problem, consider that starting from an initial state s_0 , the MDP following a policy π will result in a trajectory $\zeta = \{[s_0, a_0, r_0], [s_1, a_1, r_1], \dots\}$. Let us now define the so-called Q-function of each state-action pair (s, a) under policy π as the expected sum of discounted reward obtained by starting at any state s and following a policy π thereafter after taking the action $a = \pi(s)$:

$$Q^\pi(s, a) = E_\pi \left[\sum_{k=0}^{\infty} \gamma^k r(s_k, a_k) | s_0 = s \right]. \quad (1)$$

Note here that the expectation is on π , that is, following a different policy will lead to a different expected Q-value even when one starts on the same state. The Q-function is defined slightly (but very importantly) different than the V-function or the value function V^π for each state s under policy π . The value function is defined only over s (and not over (s, a)) as $V^\pi(s) = E_\pi[\sum_{k=0}^{\infty} \gamma^k r(s_k, a_k) | s_0 = s]$. That is, it is defined simply as the expected sum of discounted rewards obtained by following the policy π starting from the state s . The goal is to find the optimal policy that maximizes the expected cumulative discounted reward in all states, that is, to find $\pi^*(s) = \arg \max_\pi V^\pi(s)$. Here note that the maximum is over the policy π . The value function of the optimal policy π^* is termed as V^* .

The Bellman equation states that the value of taking action a_k in state s_k under the policy π equals the sum of the immediate reward and the discounted value achieved by following the policy π :

$$Q^\pi(s_k, a_k) = r(s_k, a_k) + \gamma Q^\pi(s_k, \pi(s_k, a_k)). \quad (2)$$

It is rather straightforward to derive this equation, by noting that $Q^\pi(s_k, a_k) = \sum_{k=0}^{\infty} \gamma^k r(s_k, a_k) =$

$r(s_k, a_k) + \gamma \sum_{k=1}^{\infty} \gamma^{k-1} r(s_k, \pi(s_k))$. Further expanding the sum leads to the recursion in (2).

Similarly, it can be shown that the optimal Q function Q^* follows the Bellman optimality equation $Q^*(x, a) = r(x, a) + \gamma \max_{a'} Q^*(x, a')$. The V -function also satisfies the optimality equation $V^*(s_k) = \max_a (r(s_k, a_k) + \gamma V^*(s_{k+1}))$; however note that to find the optimal action, the knowledge of s_{k+1} or alternatively $\mathcal{P}$ is necessary. On the other hand, with the Q -function

$$\pi^*(s_k) = \arg \max_a Q^*(s_k, a). \quad (3)$$

What we have presented is one of the most commonly studied MDP formulations. One key variant is the formulation with stochastic policies, where the policy is a distribution over actions, and given a state s_k , the action is sampled from the policy distribution $a_k \sim \pi(s_k)$.

There are many algorithms available to solve the MDP problem in the dynamic programming setting when $\mathcal{R}$ and $\mathcal{P}$ are known. Most of these leverage the fact that the recursion in Equation 2 is a contraction. Therefore starting with any policy π , it is possible to follow first a policy evaluation step to populate the V - or the Q -function and then a policy improvement step where for each state the policy $\pi(s) \leftarrow \arg \max_{a \in \mathcal{A}} \sum_{s' \in \mathcal{S}} \mathcal{P}(r(s, a) + \gamma V^\pi(s'))$. Several of these algorithms are discussed in detail in Geramifard et al. (2013).

In this entry, we focus on the so-called reinforcement learning (RL) problem, in which $\mathcal{R}$ and $\mathcal{P}$ are assumed to be unknown, and the agent figures out an optimal policy through experience. There are many algorithms available to solve the RL problem, some of which are summarized in Fig. 1. We provide details of some key methods now.

Q-Learning and Other Value-Based Methods

Using the Markov assumption on the transition model and the Bellman formula, recursive update expression for learning the state-action value function $Q^\pi(s_t, a_t)$ can be defined as

$$Q^\pi(s_k, a_k) = r(s_k, a_k) + \gamma Q^\pi(s_{k+1}, \pi(s_{k+1}))$$

The above definition leads us to the famous Q-learning and SARSA algorithms, which use the following update form

$$Q^\pi(s_k, a_k) \leftarrow Q^\pi(s_k, a_k) + \alpha \delta$$

where α is the learning rate and δ is defined as temporal-difference (TD-error). Different choice of TD δ error leads to different algorithm

- Q-Learning: $\delta = r(s_k, a_k) + \gamma \max_a Q^\pi(s_{k+1}, a) - Q^\pi(s_k, a_k)$
- SARSA: $\delta = r(s_k, a_k) + \gamma Q^\pi(s_{k+1}, \pi(s_{k+1})) - Q^\pi(s_k, a_k)$

For large or continuous state-action spaces, a tabular representation quickly becomes intractable (Geramifard et al. 2013). This issue can be resolved by using a function approximator, such as linear function approximators (Geramifard et al. 2013), Gaussian processes (Chowdhary et al. 2014; Liu et al. 2018; Kuss 2006), or neural networks (Mnih et al. 2015, 2016; Bertsekas and Tsitsiklis 1996; Schulman et al. 2017, 2015b). Deep Q-networks (DQN) is one such algorithm that has solved instability issues of approximate Q-learning with deep neural network function approximators and techniques like experience replay and soft update of the network (Mnih et al. 2015). DQN uses a cost function of the form

$$J(\theta) = \mathbb{E}_{\{s, a, r, s'\} \sim \mathcal{B}} \left(r + \gamma \max_{a'} Q(s', a', \theta^-) - Q(s, a, \theta) \right)^2$$

where the samples $\{s, a, r, s'\}$ are drawn from the replay buffer $\mathcal{B}$ and θ^- is frozen network parameter from last update.

Policy Gradient (PG) and Actor-Critic Methods

Policy gradient method aims at optimizing a parameterized policy $\pi_\theta(a_t | s_t)$ resulting in the higher total discounted return. The total discounted return the policy gradient aims to

Reinforcement Learning and Adaptive Control,

et al. (2014), PEGASUS Ng and Jordan (2000), PILCO Deisenroth and Rasmussen (2011), PPO Schulman et al. (2017), REINFORCE Sutton et al. (2000), TRPO Schulman et al. (2015b)

R

maximize is defined as

$$J(\theta) = \mathbb{E}_{\tau \sim \pi_{\theta}(\tau)} \left[\sum_{\tau} r(s_k, a_k) \right]$$

where the $\pi_{\theta}(\tau)$ is the probability of the trajectory and is defined as

$$\begin{aligned} \pi_{\theta}(\tau) &= \pi_{\theta}(s_0, a_0, \dots, s_T, a_T) \\ &= \rho(s_0) \prod_{k=1}^T \pi_{\theta}(a_k | s_k) p(s_{k+1} | s_k, a_k) \end{aligned}$$

PG uses gradient ascent for maximizing the total expected return $J(\theta)$. The policy gradient update is given as

$$\theta = \theta + \alpha \nabla_{\theta} J(\theta)$$

where $\nabla_{\theta} = \mathbb{E}_{\tau \sim \pi_{\theta}(\tau)} [\nabla_{\theta} \log \pi_{\theta}(\tau) R(\tau)]$. The gradient calculation using likelihood ratio is first introduced in REINFORCE paper by Williams et al. (Sutton et al. 2000). This method makes use of likelihood ratio trick given by identity $\nabla_{\theta} \pi_{\theta}(\tau) = \pi_{\theta}(\tau) \nabla_{\theta} \log \pi_{\theta}(\tau)$ in policy-gradient theorem.

Several variants of the policy gradient can be constructed by replacing the total return performance metric in the gradient expression as follows: (Schulman et al. 2015a)

$$\nabla_{\theta} = \mathbb{E}_{\tau \sim \pi_{\theta}(\tau)} [\nabla_{\theta} \log \pi_{\theta}(\tau) \zeta(\tau)].$$

Let $\zeta(\tau)$ be the placeholder for total return. Using different estimates of the total return, we can build different policy gradient algorithms, for example, $\zeta \tau = R(\tau) = \sum_{k=1}^T r(s_k, a_k)$ is the vanilla REINFORCE algorithm which uses bootstrapped total return on trajectory. The causality correction to the total return estimate for gradient variance reduction in REINFORCE uses $\zeta \tau = \sum_{k'=1}^T r(s_{k'}, a_{k'})$ (Sutton et al. 2000). A baseline corrected return for variance reduction of gradient estimate employs $\zeta \tau = \sum_{k=1}^T r(s_k, a_k) - b_k$, where b_k can be average reward (Peters and Schaal 2006). An actor-critic algorithm uses $\zeta \tau = Q^{\pi}(s_k, a_k)$ (Peters and Schaal 2008), while an advantage actor-critic algorithm would use $\zeta \tau = A^{\pi}(s_k, a_k)$, where A^{π} is the advantage function (Mnih et al. 2016).

Model-Based RL or “Indirect RL”

In model-based RL a goal is to attempt to learn $\mathcal{T}$ and $\mathcal{R}$ from state-action-reward tuples and use this in learning the policy. Once $\mathcal{T}$ and $\mathcal{R}$ are learned, they may be used in any capacity to solve the MDP. The open-ended nature of how to use the model in this setting has brought about much debate and discussion on what constitutes model-based RL, as one could argue that model-free uses the value function and MDP assumption as a “model.” Generally model-based RL aims take advantage of structure in the dynamics and cost model resulting in orders of magnitude improvements in data efficiency over model-free methods, which is essential for some real-world applications. Modern methods typically fall under two different approaches. The first category strongly resembles system identification where one iteratively estimates a global dynamics model through interactions and uses the model to plan an optimal policy as in model predictive control (MPC), usually via a shooting method. One example is probabilistic ensembles with trajectory sampling (PETS) (Chua et al. 2018): a probabilistic

dynamic model is learned via a model ensemble through environment interactions. The optimal control is given by a sampling-based shooting method using the learned probabilistic model. Another approach is data-efficient reinforcement learning with probabilistic model predictive control (Kamthe and Deisenroth 2018): a probabilistic model is learned using a Gaussian process in order to account for long-term prediction uncertainty. The optimal control is found using MPC and analytic gradients computed via maximum principle.

The second category makes use of global or local models to do policy optimization directly as in the model-free case either by using the model derivatives to compute analytic policy updates or sampling the update using the learned dynamics model. In probabilistic inference for learning control (PILCO) (Deisenroth and Rasmussen 2011), a probabilistic model is learned using a Gaussian process and exploits analytic gradients of resulting distribution to optimize the policy. In Guided Policy Search (GPS) (Levine and Koltun 2013), locally linearized models of the dynamics and cost function are used to iteratively update a global policy.

The model-based assumption can also become a detriment. The policy is biased by the chosen model parameterization and data distribution and may result in compounding errors in planning or poor local solutions in policy optimization. This is why the most successful model-based methods emphasize model uncertainty representation. Many ongoing works aim to investigate how to most effectively and generally exploit model assumptions and scale to arbitrarily problems with high-dimensional observations.

Connections Between RL and Adaptive Control

Both RL and adaptive control are frameworks designed to find control policies when the model transitions are not known. Adaptive control has classically considered control of continuous-time systems using state-space models and well-defined tracking objectives (Tao 2003; Narendra and Balakrishnan 1997; Chowdhary et al. 2015;

Calise et al. 2001; Åström and Wittenmark 1995), while RL has classically focused on decision-making policies in discrete-state MDPs. The key power of RL is that reward can be sparse or “delayed,” that is, the agent does not need to have a reward at every time step k , rather only in certain states. For example, an agent trying to find a path on a map need only obtain the reward when it reaches its goal, and not necessarily along the way. This is in contrast with traditional adaptive control problems such as model reference adaptive control in which the agent receives a tracking error reward at every time step. Traditionally, continuous-time RL problems are considered difficult to solve due to (1.) challenges in learning the right approximate representation for continuous domain state-action spaces (Geramifard et al. 2013; Kaelbling et al. 1996, 1998; Sutton and Barto 1998) and (2.) excessive number of experiments required to handle the explore-exploit dilemma in continuous state spaces (Sutton and Barto 1998; Busoniu et al. 2010; Axelrod and Chowdhary 2015). Recently advances in computing power and training of deep neural networks for supervised learning have rekindled and fueled a number of works focused on solving continuous-time control problems with RL in simulation (Duan et al. 2016; Lillicrap et al. 2015). The results are promising, given that the agent can learn high-dimensional control tasks merely from trials; however, transition from simulation to real world has been a challenge, especially in the face of results that show that the learned policies may not transfer well across similar systems or degrade rapidly when parameters are only slightly varied. In essence, these works have focused on learning control policies through experience, but are not yet equipped to adapt the policies in face of change. There has been interest in also using the RL frameworks for solving classical control problems (Lewis et al. 2012; Modares et al. 2014; Kiumarsi et al. 2014).

Summary and Future Directions

In summary, given enough samples and time, RL can learn policies for complex tasks. However,

much work remains to be done in figuring out principled mechanisms to quickly and efficiently transfer policies learned between domains to bring RL to the real world. A significant body of literature on transfer in RL is focused on initialized RL in the target domain using learned source policy, known as jump-start/warm-start methods (Taylor et al. 1999, 2005; Ammar et al. 2012, 2015; Banerjee and Stone 2007; Peters and Schaal 2006; Peng et al. 2017b; Ross et al. 2011; Yan et al. 2017). However, warm-start, which has been reasonably successful for supervised learning, can often lead to mixed and even negative results in RL (Joshi and Chowdhary 2018; Taylor and Stone 2009). Efforts are also being made in exploring accelerated learning directly on real robots, through Guided Policy Search (GPS) (Levine et al. 2015), and parallelizing the training across multiple agents using meta-learning (Levine et al. 2016; Nagabandi et al. 2018; Zhu et al. 2018). However, these and other reported architectures do not *necessarily* lead to improved sample efficiency, nor are guaranteed to handle relatively minor changes in the transition model, and are even known to cause negative transfer. In essence, many exciting research directions remain in ensuring RL fails gracefully when the underlying model changes or has robustness margins like linear controllers. Hierarchical RL and behavioral adaptation are accordingly also receiving increasing attention (Joshi and Chowdhary 2018).

Reinforcement Learning for Approximate Optimal Control

R

Abstract

Approximate dynamic programming is an approach to balance computational demands with optimal decision-making. Dynamic programming is a feedback control method that generates an optimal policy, which is obtained by solving the Hamilton-Jacobi-Bellman

(HJB) equation. Since the solution to the HJB is intractable in general and requires exact knowledge of the system dynamics, actor-critic-based reinforcement learning (RL) methods can be used to approximate the value function and, hence, the optimal controller. Emerging advances in approximate dynamic programming are described that focus on the computational expense to minimize a defined cost functional, including RL approaches that seek to rapidly identify the optimal value function.

Introduction

Optimal control problems focus on minimizing a trade-off between an end goal and the action required to reach the goal. Mathematically, for a controlled dynamical system such as

$$\dot{x}(t) = f(x(t)) + g(x(t))u(t), \quad (1)$$

where $f : \mathbb{R}^n \rightarrow \mathbb{R}^n$ and $g : \mathbb{R}^n \rightarrow \mathbb{R}^{n \times m}$ are locally Lipschitz functions, $x : \mathbb{R}_{\geq t_0} \rightarrow \mathbb{R}^n$ denotes the system state, $u : \mathbb{R}_{\geq t_0} \rightarrow U \subset \mathbb{R}^m$ denotes the control input, and U denotes the action space, the objective for optimal control problems can be stated as the desire to minimize a cost functional such as

$$J(t_0, x_0, u) = \int_{t_0}^{t_f} L(x(t), u(t), t) dt + \Phi(x(t_f)), \quad (2)$$

under a set of constraints (e.g., dynamics of the state, state boundaries, and limits on the input rate or magnitude), where $L : \mathbb{R}^n \times U \times \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}$ is the Lagrange cost, $\Phi : \mathbb{R}^n \rightarrow \mathbb{R}$ is the Mayer cost, t_0 is the initial time, and t_f and x_f denote the final time and state, respectively. Solutions to the optimal control problem typically either use Pontryagin's maximum principle or dynamic

programming. Controllers based on the maximum principle seek to minimize (2) starting from a specific state, whereas dynamic programming yields controllers that minimize (2) starting from any state (i.e., generate optimal policies). The key difference is that the controller derived from dynamic programming is a feedback controller, in the sense that it is guaranteed to be optimal for any initial condition of the dynamical system, whereas the maximum principle generates the optimal state, co-state, and control trajectories for a given initial condition, and the resulting controller must be implemented in an open-loop manner, because if the initial condition changes, the optimal solution is no longer valid and the optimal controller must be redetermined (Kamalapurkar et al. 2018). However, developing an optimal feedback controller carries a computational cost associated with solving the Hamilton-Jacobi-Bellman (HJB) equation, which is a nonlinear partial differential equation that involves exponential growth in numerical complexity as the dimension of the state space increases. Given the complexity of solving the HJB equation, this entry focuses on approximate dynamic programming (ADP) using reinforcement learning (RL) as a framework for developing a controller to minimize the unconstrained infinite-horizon cost given by

$$J(t_0, x_0, u) = \int_{t_0}^{\infty} Q(x(\tau)) + u^T(\tau)Ru(\tau)d\tau, \quad (3)$$

where $Q : \mathbb{R}^n \rightarrow \mathbb{R}$ is a positive definite function and $R \in \mathbb{R}^{m \times m}$ is a symmetric positive definite matrix. For nonlinear systems that are affine in the controller as in (1) with cost functions that are quadratic in the controller as in (3), under the assumptions that at least one admissible controller exists and the optimal control problem has a continuously differentiable value function, the controller $u(t) = u^*(x(t))$ where the policy $u^* : \mathbb{R}^n \rightarrow \mathbb{R}^m$ is defined as

$$u^*(x) = -\frac{1}{2}R^{-1}g^T(x)(\nabla_x V^*(x))^T \quad (4)$$

is the optimal controller, where $V^*(x)$ is the time-independent optimal value function (i.e., cost-to-go) given by

$$V^*(x) \triangleq \inf_{u[t,\infty]} J(t, x, u). \quad (5)$$

Dynamic Programming Overview

For systems with finite state and action spaces, dynamic programming techniques such as policy iteration and value iteration (Bertsekas and Tsitsiklis 1996; Sutton and Barto 1998) are effective methods for optimal control synthesis, although drawbacks include the aforementioned curse of dimensionality and the need for perfect knowledge of the dynamics. Iterative/recursive (also called simulation-based) RL techniques such as Q-learning and temporal difference learning (Sutton and Barto 1998) avoid the need for exact model knowledge. Neuro-dynamic programming (cf. Werbos et al. 1992; Bertsekas and Tsitsiklis 1996 and the references therein) extends such methods to general finite state spaces through parametric approximation of the policy, replacing the arbitrarily large state space with a compact set of weights that encode the value function. Actor-critic RL is a popular method for generalized policy iteration algorithms: detailed reviews of actor-critic methods are provided in Kamalapurkar et al. (2018), Grondman et al. (2012), and Lewis and Liu (2013). In these methods, the critic estimates the value function (e.g., through temporal difference or heuristic dynamic programming), and the actor directly minimizes the estimated value function or the Bellman error (also known as the temporal difference error). The iterative nature of actor-critic methods is amenable to and has fueled a growing interest in discrete-time approximate optimal control problems over the past decade (Bhatnagar et al. 2009; Kiumarsi et al. 2017). Extensions to continuous time domains are also an active open area of research with recent advances providing convergence and stability guarantees (e.g., through a Lyapunov-based analysis) that dictate the design

of adaptive updates that adjust the actor and critic estimates.

Actor-Critic Approximation

In an approximate actor-critic-based solution, the optimal value function is replaced by a parametric estimate such as $\hat{V}(x, \hat{W}_c) \triangleq \hat{W}_c^T \sigma(x)$, and the optimal policy is replaced by a parametric estimate such as $\hat{u}(x, \hat{W}_a) \triangleq -\frac{1}{2} R^{-1} g(x)^T \nabla_x \sigma^T(x) \hat{W}_a$ where $\hat{W}_c \in \mathbb{R}^L$ and $\hat{W}_a \in \mathbb{R}^L$ denote vectors of estimates of the ideal parameters for the critic and actor, respectively, $\sigma: \mathbb{R}^n \rightarrow \mathbb{R}^L$ is a continuously differentiable nonlinear activation function, and L denotes the number of unknown parameters. After replacing the optimal controller and ideal value function in (4) and (5), respectively, with their estimates, the resulting Bellman error $\delta: \mathbb{R}^n \times \mathbb{R}^L \times \mathbb{R}^L \rightarrow \mathbb{R}$ is defined as

$$\begin{aligned} \delta(x, \hat{W}_c, \hat{W}_a) \triangleq & \nabla_x \hat{V}(x, \hat{W}_c) (f(x) \\ & + g(x) \hat{u}(x, \hat{W}_a)) \\ & + L(x, \hat{u}(x, \hat{W}_a)), \end{aligned} \quad (6)$$

where $\delta(x(t), \hat{W}_c(t), \hat{W}_a(t)) = 0$ when the approximations are exact (i.e., the Bellman error provides a measure of suboptimality). Computation of the Bellman error in (6) requires exact knowledge of (1). To provide robustness to uncertainty in (1), integral RL (e.g., Chapter 3 of Vrabie et al. 2013) is a method that uses an integral form of the HJB equation. An alternative approach is to estimate the state derivative directly as in Bhasin et al. (2013), where the critic computes the Bellman error at each time instance using an estimate of the state derivative. Another alternative is to simultaneously learn the dynamics while also learning the value function and hence optimal policy (e.g., an actor-critic-identifier strategy Bhasin et al. 2013). Such methods highlight the complexity of simultaneously producing an admissible policy while adapting

to uncertainty in the dynamics and learning the optimal policy.

In real-time implementations of RL, the approximated policy is used to control the system; therefore, both stability and optimality concerns dictate the need to obtain a good approximation of the value function (i.e., system identification in the sense that the approximated parameters converge to the ideal parameters). Typically, the objective in adaptive control problems is simply boundedness of the parameter estimates, and convergence to the actual parameters is achieved only if a sufficient exploration condition (i.e., persistence of excitation (PE)) is satisfied. In general, and especially for nonlinear systems, the traditional PE condition is impossible to guarantee a priori or verify during execution. Hence, stochastic systems pursue a randomized stationary policy, and an ad hoc exploration signal is often added for deterministic systems, but the type of signal and length of time a signal should be added are unsolved problems. Moreover, to approximate the total cost over an operating domain, the whole domain should be explored (i.e., $x(t)$ should pass through the entire operating domain) for the critic to learn the value function. The trade-off between the need to explore the operating domain to exactly learn the value function versus the need to perform actions to minimize the cost is the classic exploration versus exploitation problem.

For model-free approaches (e.g., integral RL), exploration conditions can be relaxed using experience replay Modares et al. (2014), where each evaluation of the Bellman error is stored in a history stack; however, a finite amount of exploration is still required since the values stored in the history stack are also constrained to the system trajectory. Similar strategies have been explored for stochastic systems by solving the optimal control problem off-line in the sense that repeated learning trials need to be performed before the algorithm learns the controller. Such model-free approaches are often limited to on-policy learning, in the sense that the integral Bellman error is only meaningful if it is evaluated along the system trajectories, and likewise, state derivative estimators can only generate numerical

estimates of the state derivative along the system trajectories.

Model-based approaches have the advantage that the model can be used to evaluate the Bellman error at any number of desired points in the state space. Specifically, the state derivative and, hence, the Bellman error can be evaluated at any point in the domain. As described in Kamalapurkar et al. (2018), the use of a model to evaluate the Bellman error at an unexplored point in the state space can be interpreted as a simulation of experience (i.e., the value function can be estimated at any arbitrary point x_i in the state space without actually visiting x_i). The ability to learn the value function from off-policy exploration provides a parallelization of learning that results in simultaneous exploration and exploitation. These methods can even be exploited when the model is uncertain through actor-critic-identifier methods (Bhasin et al. 2013). Concurrent learning (Chowdhary and Johnson 2011; Parikh et al. 2019) is a process where each input-output data point is stored in a history stack that can be used to formulate a PE-like condition to determine sufficient exploration. The significant advantage of concurrent learning is that the resulting sufficient excitation condition involves a minimum eigenvalue computed over a summation of data. While the time (or number of data points) required to obtain sufficient excitation is unknown a priori, the condition can be checked at each time instance and verified online, allowing exponential convergence of the value function approximates to the actual value function.

Summary and Future Directions

By its very nature, optimal control involves a trade-off between a goal and the effort to obtain the goal, encoded in a cost functional. Approximate optimal control methods are motivated by a further trade-off between the minimal cost and the required computational resources and hence time required to make a decision. RL-based ADP methods are a mainstream research focus that offsets the computational demands associated with

a continuous state space by a parameterization of the optimal value function by a finite set of weights and basic functions. The challenge in such problems is to minimize the cost by rapidly learning the exact value function (and potentially the system dynamics). As described previously, to resolve the resulting exploration versus exploitation conundrum, new research directions are exploiting parallelized/concurrent learning to simultaneously execute actions while learning the uncertainty, including the use of stored data and extrapolation of states for off-policy learning (Sledge et al. 2018; Chowdhary et al. 2013; Wawrzyński 2009). Additional emerging directions include learning methods that yield finite-time learning (cf. Gupta et al. 2019; Hong et al. 2006; Karafyllis and Krstic 2018). Such methods could facilitate learning for finite-time optimal control problems and can potentially enable the inclusion of more complex problems that involve a hybrid mixture of continuous and discrete dynamics where switching occurs between subsystems, which may involve the development of dwell-time conditions.

Abstract

This entry provides a short introduction to a class of reinforcement learning algorithms, in particular value function approximation, applied to stochastic optimal control problems. The entry demonstrates how core ideas from dynamic programming and Bellman equations are utilized in common data-driven reinforcement learning algorithms, as well as discuss fundamental challenges of the approach.

Keywords

Optimal control · Stochastic control · Machine learning · Reinforcement learning

Introduction

Sequential decision-making problems under uncertainty are a general class of problems encountered in engineering practice. Stochastic optimal control theory provides a classical way of formalizing such problems. The major outcome of this theory is the development of dynamic programming algorithms which can be used to find optimal solutions. In practice however dynamic programming algorithms have

high computational complexity and can be used primarily in problems with finite and relatively small state and action spaces, excluding higher dimensional and continuous control problems. Moreover, classical dynamic programming is developed based on a known model of the dynamics and the evolution of the system. This assumption is challenging in practice where a system is not completely known a priori or subject to changes and disturbances.

Reinforcement learning is a collection of data-driven algorithms that have been proposed to address the above challenges. Data in this context usually involve trajectories of the system to be controlled over time and associated costs. Given such data, and often without explicit knowledge of the system description, these algorithms aim to find good control policies. Such approaches have gained particular interest in recent years due to the advancements in computing resources as well as the development of efficient machine learning architectures, such as neural networks (LeCun et al. 2015). Examples of the success of the reinforcement learning approach are using neural networks to learn how to play video games from pixels (Mnih et al. 2015) and in the game of Go (Silver et al. 2016), as well as in robotics (Levine et al. 2016). This article focuses on value function approximation algorithms, while policy search methods constitute a separate class of algorithms in the literature (Bertsekas 2015; Sutton and Barto 2018).

Reinforcement Learning for Control Using Value Function Approximation

The approach follows a stochastic optimal control problem formulation. The interest is in controlling a dynamical system of the form

$$x_{k+1} = f(x_k, u_k, w_k), \quad (1)$$

where x_k is the system state taking values in general in (or a subset of) $\mathbb{R}^n$, u_k is the control input taking values in general in (or a subset of) $\mathbb{R}^m$, and w_k is a noise term, typically modeled as an independent and identically distributed random

variable. There is also a given scalar *cost function at each time step* $c(x_k, u_k)$. This is an important part of the problem formulation, as the scalar cost function is the main mechanism for enforcing some desired control behavior; hence it should capture all information relevant to achieving a task.

The goal is to choose the control inputs $u_k, k \geq 0$ as a function of current state, or in other words optimize over the control policy denoted by $u_k = \pi(x_k)$. The criterion for choosing the control policy is the cost accumulated over time. This entry studies an infinite horizon cost discounted by a factor $\gamma \in (0, 1)$ defined as

$$\mathbb{E} \sum_{k=0}^{\infty} \gamma^k c(x_k, u_k), \quad (2)$$

and the approach can be similarly followed for minimizing finite horizon, undiscounted, or average costs (Bertsekas 2015). The standard linear quadratic regulator is a particular example of this problem with a closed form solution. The approach to find the optimal policy described in this entry is based on learning value functions from data, that is, trajectories sampled from the system dynamics. As a first step, we consider the problem of computing the cost associated with following a fixed control policy. This step is called *policy evaluation*. Then a procedure to search for an optimal policy is described.

Policy Evaluation by Value Function Approximation

For any policy π , suboptimal in general, there is a function, called the value function V_π , which expresses the future expected cost starting from a point $x \in \mathbb{R}^n$ and following the policy π , i.e.,

$$V_\pi(x) = \mathbb{E}^\pi \left[\sum_{k=0}^{\infty} \gamma^k c(x_k, u_k) \middle| x_0 = x \right], \quad (3)$$

From standard dynamic programming arguments for such a function, it holds that

$$\begin{aligned} V_\pi(x_k) &= c(x_k, \pi(x_k)) \\ &\quad + \gamma \mathbb{E}_{w_k} [V_\pi(x_{k+1}) \mid x_k, u = \pi(x_k)] \end{aligned} \quad (4)$$

for all $x_k \in \mathbb{R}^n$. This is called the *Bellman equation* for the given control policy π . The Bellman equation is a functional equation, and it is hard to solve for the desired value function V_π even if the dynamics are available. This issue is commonly referred to as the curse of dimensionality.

To alleviate the curse of dimensionality, an alternative approach is to search for an approximate solution to this equation based on data. Specifically, a *family of functions* $V(x; \theta)$ described by a set of parameters θ taking values in some subset of $\mathbb{R}^p$ is commonly assumed, and then the problem is relaxed to just searching for appropriate values for θ . A special case is a linear parametrization $V(x; \theta) = \sum_{i=1}^p \phi_i(x) \theta_i = \phi(x)^T \theta$ where $\phi_i(x)$ are fixed functions, often referred to as features of the state. Examples include the following:

- One simple approach is to discretize the state space and search within the family of functions that are piecewise constant on the discretized space. For example, if $x_k \in [0, 1]$ and we discretize the space evenly in $p = 2^L$ segments, then define $V(x; \theta) = \sum_{i=1}^{2^L} \theta_i \mathbb{I}(x \in [(i-1)2^{-L} \leq x \leq i2^{-L}])$ using an indicator function notation. This is a special case of a linear approximation. Discretization is a general approach but does not scale well for higher-dimensional state spaces (curse of dimensionality).
- A linear combination of Fourier basis functions or radial basis functions may be used as the family of value functions (Sutton and Barto 2018, Ch. 9).
- A linear combination of polynomials of the state x up to some fixed degree may be used for $V(x; \theta)$. As an example, in the case of the linear quadratic control problem, it is well-known that the value functions of linear policies are quadratic functions; hence it suffices to approximate over the family of quadratic value functions.
- A neural network with multiple layers may be used for $V(x; \theta)$ where x is the input and θ is the collection of weights across all layers (Sutton and Barto 2018; Silver et al. 2016).

The data that are used to find the parameters of a value function approximation are typically trajectories of the dynamical system and the cost generated by following the policy that one is interested in evaluating. More specifically they are of the form

$$\{x_0, u_0, c_0, x_1, u_1, c_1, \dots, x_N\}. \quad (5)$$

That is, an initial starting state x_0 is selected, then the control input $u_0 = \pi(x_0)$ is applied to the system following the policy, and the current cost $c_0 = c(x_0, u_0)$ is obtained, as well as the next random state x_1 following the system dynamics (1), and the process repeats till some time N . For simplicity of exposition, this entry discusses the case where a single trajectory is given. In practice one creates a pool of multiple trajectories from potentially different initial points and processes parts of these collection of trajectories at random. The procedure that generates the data/trajectories can be, for example, a simulation of the system dynamics assuming that it is available, or a physical experiment. It is also worth noting that in this setup, the cost c_k per time step could also be measured directly (in simulation or experiment), rather than computed from a known cost function.

With the collected data points following the policy, one needs to find the parameters θ of the value function family that better fit the Bellman equation. A simple criterion for this is to compute the parameters that minimize the average square error in Bellman equation (4) as in

$$\text{minimize}_{\theta} \sum_{k=1}^{N-1} (V(x_k; \theta) - c_k - \gamma V(x_{k+1}; \theta))^2. \quad (6)$$

Standard gradient descent can be used to find a local optimum of this criterion, or variants such as stochastic gradient descent where only few samples are selected at random from the pool of data to approximate the gradient. Regularization terms on θ may also be added in (6) to avoid overfitting to data.

From a computation point of view, it is useful to note that in the special case of approximating

the value function as a linear combination of basis functions, the above process simplifies to a (convex) quadratic optimization problem

$$\text{minimize}_{\theta} \sum_{k=1}^{N-1} \left(\phi(x_k)^T \theta - c_k - \gamma \phi(x_{k+1})^T \theta \right)^2. \quad (7)$$

The optimal solution θ satisfies the p -dimensional linear system of equations

$$\begin{aligned} & \sum_{k=0}^{N-1} (\phi(x_k) - \gamma \phi(x_{k+1})) (\phi(x_k) - \gamma \phi(x_{k+1}))^T \theta \\ &= \sum_{k=0}^{N-1} c_k (\phi(x_k) - \gamma \phi(x_{k+1})), \end{aligned} \quad (8)$$

and the solution is unique under standard rank conditions and can be readily computed either by directly solving the above equation or by gradient descent.

It is intuitively clear that in order to obtain a better fit to the Bellman equation, one needs to use rich enough samples where x_k spans a large area of the state space. However samples are generated following a given policy; hence fewer data will be generated at parts of the state space that are visited less often by the policy. This is an exploration problem. A typical mechanism to alleviate this problem is to pick a policy π that includes some randomness to promote exploration of the state space. For example, the policy may include an additive i.i.d. noise. At a high level, this is related to the notions of persistently exciting inputs in adaptive control and system identification (Kumar and Varaiya 2015).

Beyond the simple square Bellman error in (6), other criteria may be used to learn the parameters θ . A more commonly used approach for linear value function approximations is to solve what is termed *projected Bellman equation* – see, for example, (Bertsekas 2015, Ch. 6) and (Sutton and Barto 2018, Ch. 11). Moreover the above discussion is for an offline setup where a batch of data/trajectories are available to process, while alternatively online algorithms have been proposed where iteratively at each step, only

the currently observed data sample is processed in order to find the appropriate value function approximation (Sutton et al. 2009).

Policy Optimization by Value Function Approximation

Building upon the previous section, one can devise a procedure to approximately search for optimal policies. There is one extra technical step that needs to be added. Beyond the value function that depends on each state, it is also possible to define a function that depends on both the state and the control input and is commonly referred to as the Q-function. Specifically for any control policy π , there exists a function $Q_\pi : \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}$ such that

$$Q_\pi(x_k, u_k) = c(x_k, u_k) + \gamma \mathbb{E}_{w_k} [Q(x_{k+1}, \pi(x_{k+1})) | x_k, u_k] \quad (9)$$

holds for all $x_k \in \mathbb{R}^n$ and all $u_k \in \mathbb{R}^m$. This is again a form of Bellman equation associated with the policy π . The approach to approximate the Q-function from data is the same as in the previous section. The first step is to collect trajectories/samples of the form

$$\{x_0, u_0, c_0, x_1, u_1, c_1, \dots, x_N\}, \quad (10)$$

following policy π and then to fit a value function on this data selected from some family of functions $Q(x, u; \theta)$ parametrized by θ . The same type of families can be employed as explained in the previous section. The main challenge is that the function that is being parametrized in this case is in general more complex as it is defined on the higher-dimensional domain of both states and inputs. To fit the parameters θ , a common approach is to similarly minimize a square Bellman error with respect to Q-functions, e.g.,

$$\begin{aligned} & \text{minimize}_{\theta} \sum_{k=1}^{N-1} (Q(x_k, u_k; \theta) - c_k \\ & - \gamma Q(x_{k+1}, u_{k+1}; \theta))^2. \end{aligned} \quad (11)$$

The main advantage of working with the Q-function of a policy π is that it becomes straightforward to obtain a new improved policy that has a lower cost. This is an iterative procedure called *policy iteration* described in Algorithm 1. In principle, assuming no approximation errors, or no randomness due to the data samples, the procedure is guaranteed to provide an improved policy at each iteration, and at least in finite state and action spaces converge to the optimal policy (Bertsekas 2015, Ch. 2). In the face of bias from the function approximation procedure and randomness from the sampled data, there are in general no guarantees of improvement or convergence, but one expects that better policies will be obtained.

Algorithm 1 Policy iteration algorithm with Q-functions

- 1: **for** Iteration $t = 1, \dots$ **do**
- 2: Collect sample trajectories $\{x_0, u_0, c_0, x_1, u_1, c_1, \dots, x_N\}$, following policy π_t
- 3: Learn an approximate Q-function Q_{π_t} of current policy from data samples, e.g., using (11)
- 4: Update policy to

$$\pi_{t+1}(x) = \operatorname{argmin}_u Q_{\pi_t}(x, u) \quad (12)$$

5: **end for**

We point out that the exploration problem discussed in the previous section is also present when trying to learn Q-functions and is even further complicated by the fact that data need to be collected from many input points $u \in \mathbb{R}^m$. Moreover, as the above algorithm shows, the standard policy iteration algorithm states that one should update the policy to a new one selected as the minimum of the approximated Q-function pointwise at each state x , and hence the new policy is deterministic. This in turn limits exploration of the state and input spaces at the next iteration. A common approach to alleviate this situation is to update to a randomized policy instead. For example a common option called ϵ -greedy is a new policy which with high probability $1 - \epsilon$ selects the minimum of the Q-function, and with

some small probability ϵ , it randomizes over possible inputs in order to explore (Sutton and Barto 2018, Ch. 2).

Finally, it is worth pointing out that performing the pointwise minimization step to obtain a new policy may be computationally hard. This is often alleviated by approximating also the policy through a different set of parameters, separate from the value function approximation parameters. This gives rise to a class of reinforcement learning algorithms called actor-critic algorithms (Sutton and Barto 2018, Ch. 13).

Summary and Future Directions

This entry describes main algorithmic approaches for solving optimal control problems using reinforcement learning and in particular value function approximation approaches. Key challenges and limitations of the approach are also discussed. Extended discussions can be found in recent books (Bertsekas 2015; Sutton and Barto 2018) and reviews (Lewis and Vrabie 2009; Buşoniu et al. 2018).

A general drawback of reinforcement learning methods, including the ones relying on value function approximation in this entry, is that they require a large number of samples, which can limit their practical use. Current efforts are focused on analyzing this sample complexity (Tu and Recht 2018; Dean et al. 2018). Moreover, safety is an important challenge in reinforcement learning approaches. Typically as the approach depends on randomly obtained data and on fitting value functions from a potentially large class of functions, the overall process lacks safety guarantees. Safety and stability properties exploiting prior system knowledge are a current research topic (Fisac et al. 2019; Berkenkamp et al. 2017; Rosolia and Borrelli 2017).

from other areas of engineering and applied science such as network reconstruction in packet data networks and network control systems. Obviously, biological applications pose unique challenges that are still open problems such as the level of noise, the often global effects of local perturbations to the network, and the curse of dimensionality which poses several problems in terms of size of the required data sets and computational complexity of the reverse engineering algorithms. In synthetic biology, feedback control strategies can be used to render the network behavior more reliable and less sensitive to unwanted noise and perturbations. Here, after reviewing some of the key approaches for network reconstruction, we highlight the different types of control approaches that can be used to control a gene regulatory network.

Keywords

Gene networks · Reverse engineering · Feedback control · Synthetic biology

Abstract

Over the past decades, increasingly larger and more complex gene regulatory networks (GRNs) have been synthesized de novo in synthetic biology or analyzed and studied in a number of different biological contexts. A crucial problem often encountered in applications is to reconstruct the structure of the regulatory interactions between genes and proteins in the network. This entails using experimental data to infer or reverse engineer the network structure by carrying out a combination of data processing and statistical analysis, model construction, and validation by comparing in silico predictions with experiments. The goal is to establish an iterative procedure so that models can be increasingly refined as experimental data becomes available. The problem of reverse engineering and modelling gene networks is an area of active research in systems and control overlapping with similar problems

Introduction

Synthetic biology is a new field of research where methods and tools from engineering are used to synthesize novel biological devices in vivo. At the core of any engineering design lies the ability of interconnecting elementary components to assemble circuits able to perform complex functions. Think of electronics where the interconnection of elementary components such as the resistors, capacitors, transistors, and inductances can be used to create logic gates, amplifiers, and other devices. In biology, gene regulatory networks that combine activation and inhibition among genes can be exploited to endow new functions to a living cell. Among the first networks to be proposed, the toggle switch and the repressilator represent cornerstones in the ability of synthetic biologists to do so as they endow a cell with the ability to store information or to oscillate.

Nature exploits gene regulations in many ways. Whether they are engineered or occur

in nature, gene regulatory networks can have complex structures, and it is essential to investigate methods to reverse engineer their structures from data. In particular, understanding the set of regulatory interactions (and their directions) in a network is essential to carry out fundamental research in systems biology and to design reliable GRNs in synthetic biology. Also, to enhance robustness of GRNs performing a desired function and compensate uncertainties and unmodelled dynamics, it is useful to construct feedback control mechanisms stabilizing their behavior in the presence of perturbations and noise.

Reverse engineering deals with these problems and in particular with the process of network inference from experimental data. As highlighted in Delgado and Gomez-Vela (2018), such an inference process relies on a Knowledge Database Discovery (KDD) workflow which involves going from data analysis to the validation of the reconstructed network models by contrasting *in silico* results with *in vivo* experimental data sets.

In this entry, we give a brief overview of the problems of reverse engineering and controlling gene regulatory networks. We discuss strategies for reconstructing the structure of a regulatory network of interest from data and give a summary of the key results concerning their control highlighting the different approaches that can be used to tackle this pressing open problem.

Reverse Engineering Methods

Reverse engineering GRNs from data involve a number of different goals and methods. Typically the key objectives of reverse engineering are (i) to reconstruct the (directed) network of interactions between genes and molecules for a GRN of interest, (ii) to derive mathematical models capturing the network behavior *in silico*, and (iii) to estimate the biochemical parameters characterizing the nature and strength of the interaction. Rather than giving an exhaustive review, we focus here on some of the key approaches used to infer the structure of a GRN from data

and derive a mathematical model able to approximate and capture the dynamics of the real network. We refer the reader for more details to the many exhaustive review papers, e.g., (Le Novère 2015; Klinger and Bluethgen 2018; Delgado and Gomez-Vela 2018; De Smet and Marchal 2010; He et al. 2009; Bansal et al. 2006, 2007).

The goal of network inference methods in computational biology is that of using data to unfold the structure of the gene regulatory network of interest, or to check in synthetic biological applications that the engineered gene interactions *in vivo* correspond to those designed and tested *in silico*. Typically, information on the network structure is obtained from gene expression data, although information can also be obtained from other omics data sets (e.g., proteomics, metabolomics, etc.).

There are currently four different approaches that can be used to reverse engineer the network from data. They can either be used alone or, more effectively, be combined to provide a more reliable reconstruction of the gene interactions in the network. The four main approaches are those based on correlation, information theoretic tools, Bayesian inference, or the use of dynamical systems and differential equations. Each is encoded in a variety of different software packages that are well described in Le Novère (2015).

Correlation and more generally statistical methods such as regression can shed light on whether two genes in the network share some regulatory features, for example, they are both up- or downregulated. Typically, these methods return undirected networks that, as noted in Le Novère (2015) are not entirely suitable to derive mathematical models. (Some methods to assign directions to links can be found in the literature, e.g., Gitter et al. 2011).

An alternative approach is to use information theoretic tools such as transfer entropy, mutual information, and their more recent variations such as causation entropy (Sun et al. 2015) that can be effectively used to reduce the number of spurious links in the reconstruction. Such methods often require steady-state expression data enabling the discovery of large GRN and are computationally less expensive than

other approaches. An example of such methods is ARACNE (Algorithm for the Reverse engineering of Accurate Cellular Network) (Margolin et al. 2006) to cite one of the earliest examples. Typically, the reconstructed networks are undirected, although some methods exist to obtain directed interactions (Feizi et al. 2013).

To overcome this problem, Bayesian inference can be used to give directed gene regulation edges in the reconstruction and decide the most likely network structure fitting the data.

Finally, methods based on dynamical systems, e.g., Gardner et al. (2003) and Tegner et al. (2003), can be used when dynamic measurements are available and the goal is to obtain information on the dynamic interactions between genes and proteins. One limitation of many of these latter approaches is the use of linear models that, while allowing inferring interactions from data, are far from capturing the complexity of the nonlinear dynamics describing the network of interest; see, for example, our own work on capturing the structure and dynamics of a synthetic network of five genes in yeast (Cantone et al. 2009). Modular response analysis (MRA) is often used in this context, whereas steady-state data is collected after node-wise perturbations of the network dynamics. The problem as highlighted in Kang et al. (2015) is often that point-wise perturbations of a biological network produce global effects that render it difficult to infer the correct interaction links among genes. Several approaches have been presented to overcome this problem or at least to limit its potential pitfalls; see, for example, the procedure proposed in Kang et al. (2015) or, more recently, in Klingler and Bluethgen (2018).

As is usual in identification and reconstruction strategies in Engineering, each of the methodologies described above has its pros and cons (Delgado and Gomez-Vela 2018). The performances of the various algorithms can be better uncovered by using common benchmarks, or golden standards, to compare their performance, for example, via the results of the DREAM challenge for network reconstruction as described in Marbach et al. (2012). Often a combination of

different reverse engineering methods is the best way forward to obtain the network structure with a higher degree of confidence.

Once the network structure has been obtained, it is possible to construct qualitative and quantitative models of the network dynamics by using mathematical modelling techniques. One of the most widely used approaches, which is also the best suited for control system design, is the use of linear or nonlinear differential equations capturing the nature of the regulatory links between genes and proteins in the network (Chen et al. 2010). Once model equations have been obtained, the next step is to estimate the model parameters from data. This can be done by using identification techniques from control theory, optimization tools, and a combination of data mining from the existing literature. Usually, it is necessary to carry out ad hoc experiments and use nonlinear optimization tools such as genetic algorithms in order to solve the problem of identifying a typically large number of parameters given the available data sets. A combination of steady state and time course experiments is often required to identify the unknown parameters in the model. The process is often cumbersome requiring a cycle of multiple iterations involving numerical simulations, data analysis, optimization, further in vivo experiments, and so on. An example highlighting the problems involved is described in Marucci et al. (2011), which details the mathematical model derivation and parameterization for the five gene regulatory network in yeast mentioned earlier in this entry. An excellent overview comparing different approaches and highlighting their strengths and weaknesses can be found in Delgado and Gomez-Vela (2018).

It is worth mentioning here that recent advances in machine learning have brought forward a new set of approaches based on the use of AI and neural models. These methods though require a large amount of data and are therefore of limited application when experimental data are cumbersome or expensive to acquire. Also, as noted in Delgado and Gomez-Vela (2018), such experiments are hard to carry out because every situation requires a different learning rate definition. Nevertheless, they allow both linear

and dynamic behavior and are suitable for both steady-state and time course expression profiles.

Controlling Gene Networks

Reverse engineering methods can yield models affected by uncertainties and unmodelled dynamics. For instance, linear models can be derived approximating the nonlinear dynamics of the network. Feedback control strategies can be used to compensate this effect and endow the network with some desired function. Control strategies for cell populations endowed with GRNs can be classified as external, internal, or multicellular (Del Vecchio et al. 2016; Del Vecchio et al. 2018).

External control is typically achieved via microfluidics and optogenetics platforms where the host cells are controlled by closing the feedback loop through some “external” devices such as a fluorescence microscope to measure the output of interest via segmentation algorithms, a PC implementing the control action, and actuated syringes or lasers providing the control input to the cells. Successful attempts to control gene expression, or even signaling pathways, via external strategies have been described in the literature (Miliadis-Argeitis et al. 2011; Toettcher et al. 2011), (Uhlendorf et al. 2012; Menolascina et al. 2014; Fiore et al. 2015, 2016; Fracassi et al. 2015). They mainly differ in the control input (osmotic pressure, light, small molecules) and the control strategy adopted. Optogenetics-based light inducible systems have been exploited to control gene expression in yeasts to regulate intracellular signaling dynamics in mammalian cells and to drive protein levels by using light-switchable two-component systems in bacteria. Microfluidic-based devices, allowing a tight control of cellular growing medium and the administration of inducer small molecules, have been successfully employed to investigate synchronization properties of synthetic biological clocks in bacterial cells (Danino et al. 2010), to control the transcription from the HOG1 promoter in yeast *S. cerevisiae* by varying the osmotic pressure (Uhlendorf et al. 2012), and, in our own work, to control

transcription from the GAL1 promoter using galactose and glucose as input (Menolascina et al. 2014). In this context control strategies that have already been described in the literature include the Proportional-Integral (PI) control and the Model Predictive Control (MPC). Also a different control strategy named Zero Average Dynamics (ZAD), an approach inspired by sliding control techniques, was also applied. A comparison between the performance of these strategies to control expression of the GAL1 promoter in yeast can be found in Fiore et al. (2015).

Internal (or embedded) control aims instead to embed all functions required to achieve the control goal within the cell membrane. The idea is to provide cells with some reference signal, encoded by an inducer molecule, for example, or an external optogenetic input, and let GRNs within the cell implement the sensing, actuation, and computation functions required to close the feedback loop. While many theoretical studies are available showing that such an approach is feasible in silico, the validation in vivo of such a technique has been somewhat limited. This is probably due to the complexity of the regulatory networks required to implement the various control functions and the subsequent metabolic burden that can be lethal for the cell. (Here by metabolic burden we mean as in Wu et al. (2016) the proportion of the resources of a host cell that are used to construct and operate engineered pathways.) A recent example of internal control that has been validated in vivo is the “antithetic feedback control” strategy recently presented in Aoki et al. (2019).

To reduce metabolic burden to the cells and enhance modularity of the control design, an alternative approach is to achieve control by assigning the different control functions to different cell populations within a microbial consortium. The idea presented in Fiore et al. (2016) is to create a consortium where one population, the “controllers,” senses and controls the output of another population, the “targets,” so that actuation, sensing, and computation are split among them; see Fig. 1. In this way, the GRNs to be embedded in each of the two types of cells become simpler, and metabolic burden

Reverse Engineering and Feedback Control of Gene Networks,

Fig. 1 Main idea (a) and schematic biological implementation (b) of multicellular control: the sensing, actuation, and computation functions are distributed across two different cell populations, the controllers and the targets communicating with each other via orthogonal quorum sensing channels. (Reprinted with permission from (Fiore et al. 2016). Copyright 2016 American Chemical Society.)

to each single cell is reduced. Also, flexibility and modularity of the design are enhanced as it is possible to re-use controller cells to tame the dynamics of a different cell population simply by replacing the targets with another population of interest. A crucial challenge in order to establish the control loop is that the two populations need to communicate with each other so that the control input, $\hat{u}$, can be sent from the controllers to the targets and the process output, $\hat{y}$, can be fed back from the targets to the controllers. Also the controllers must be able to sense the target outputs, compare it with some reference signal of interest, and vary their output accordingly.

Multicellular control strategies can be employed to enable cellular functions over space, for example, to induce spatial patterns for coordinated self-organization of cells, thus mimicking developmental processes (Arcak 2012; Del Vecchio et al. 2016). Control strategies across multiple populations have been utilized to control cell growth and maintain populations' size at a desired equilibrium (Scott et al. 2017). For example, in You et al. (2004), a population control circuit is proposed in silico to autonomously maintain the density of *E. coli* at a

desired level, a goal also achieved more recently in Ren et al. (2017) where feedback control across two populations was used for controlling the population size of a microbial culture through the production of toxins and anti-toxins between the populations. While having been tested in a number of scenarios in silico, multicellular control has not been fully implemented in vivo yet. Also, in silico validation often relies on the use of aggregate deterministic models or agent-based simulations. Hence, the full experimental implementation and validation of a multicellular control strategy remains a crucial open problem as well as its modelling via approaches that can fully take into account the unavoidable stochastic and spatial distribution effects it entails.

Summary and Future Directions

The increasing successes of computational biology will make computational tools such as reverse engineering methods and control strategies more and more likely to be used in practical applications. As highlighted above, a key open problem is the curse of dimensionality

that affects all the proposed methods. As the complexity of the networks of interest increases, the computational complexity of the reconstruction methods and the requirement for larger and larger data sets become a pressing open problem. Also, better methods to obtain directed regulatory links are needed and to avoid the presence of spurious links due to global effects of modular response analysis or other “local” perturbation techniques. From the control viewpoint, some crucial open challenges remain, for instance, the in vivo validation of all the proposed implementations (external, internal, or multicellular) of a feedback control strategy to regulate the behavior of a GRN of interest via appropriate inducible promoters.

Risk-Sensitive Stochastic Control

Hideo Nagai

Department of Mathematics, Kansai University,
Osaka, Japan

Abstract

Motivated by understanding “robustness” from the viewpoints of stochastic control, the studies of risk-sensitive control have been developed. The idea was applied to portfolio optimization problems in mathematical finance, from which new kinds of problem on stochastic control, named “large deviation control,” have been brought and currently the studies are in progress.

Keywords

Robustness · Mathematical finance · Large deviation control

Risk-Sensitive Criterion

Risk-sensitive stochastic control has the criterion

$$J(x, 0; T; \gamma) = \frac{1}{\gamma} \log E \left[e^{\gamma \left\{ \int_0^T f(X_s, u_s) ds + \varphi(X_T) \right\}} \right] \quad (1)$$

with $\gamma \neq 0$, where X_t is the state variable process defined by the controlled stochastic differential equation

$$dX_t = \sigma(X_t)dB_t + b(X_t, u_t)dt, \quad X_0 = x \quad (2)$$

with the control parameter process u_t . Here $\sigma(x) : R^N \mapsto R^N \otimes R^d$ and $b(x, u) : R^N \times R^m \mapsto R^N$. When $\gamma \rightarrow 0$, the criterion behaves as

$$J(x, 0; T; \gamma) \sim E \left[\int_0^T f(X_s, u_s) ds + \varphi(X_T) \right] + \frac{\gamma}{2} \text{Var} \left[\int_0^T f(X_s, u_s) ds + \varphi(X_T) \right] + O(\gamma^2).$$

Then, minimizing the criterion with $\gamma > 0$ is considered to be risk averse, while with $\gamma < 0$, it is to be risk seeking. The problem minimizing the classical criterion $E[\int_0^T f(X_s, u_s) ds + \varphi(X_T)]$ corresponds to the case of $\gamma = 0$, which is risk neutral.

When $f(x, u) = \frac{1}{2}x^*Qx + \frac{1}{2}u^*Su$, $\varphi(x) = \frac{1}{2}x^*Ux$, and $b(x, u) = Ax + Cu$, $\sigma(x) \equiv \Sigma$ with constant matrices Q, S, U, A, C, Σ , minimizing the criterion subject to the state variable processes X_t is called a linear-exponential-quadratic Gaussian (LEQG) control problem, where one may assume Q and U to be nonnegative definite and S positive definite.

H-J-B Equations

The Hamilton-Jacobi-Bellman (H-J-B) equation for the problem minimizing criterion J defined by (1) among the controlled processes governed by (2) is seen to be

$$\begin{cases} \frac{\partial v}{\partial t} + \frac{1}{2} \text{tr}[a(x)D^2v] + H(x, \nabla v) = 0 \\ v(T, x) = \varphi(x), \end{cases} \quad (3)$$

where $a(x) := (a^{ij}(x)) = ((\sigma\sigma^*)^{ij}(x))$ and

$$H(x, p) = \frac{\gamma}{2} p^* a(x) p + \inf_u \{b(x, u)^* p + f(x, u)\}.$$

In an LEQG case, where we assume that Q , U are nonnegative definite and S positive definite, the H-J-B equation has the solution expressed as:

$$v(t, x) = \frac{1}{2} x^* P(t)x + G(t),$$

by using the solutions $G(t)$ of ordinary differential equation

$$\dot{G}(t) + \frac{1}{2} \text{tr}[P \Sigma \Sigma^*] = 0, \quad G(T) = 0$$

and $P(t)$ of the Riccati equation

$$\begin{aligned} \dot{P}(t) + PA + A^*P - P(CS^{-1}C^* - \gamma \Sigma \Sigma^*)P \\ + Q = 0 \end{aligned}$$

with the terminal condition $P(T) = U$, provided that it has a nonnegative definite solution $P(t)$. However, it may occur that the Riccati equation does not have any solution if γ is large. In that case, we say that the risk-sensitive control problem “breaks down.” Namely, there is no control which makes the criterion have a finite value. On the other hand, if it has a solution, then the optimal feedback control is seen to be $-S^{-1}C^*P(t)x$, and the optimal diffusion process turns out to be the solution to

$$dX_t = \Sigma dB_t + (AX_t - CS^{-1}C^*X_t)dt, \quad X_0 = x.$$

The situation can extend to certain general cases. Under sufficiently general conditions, one can

say that if H-J-B equation (3) has a solution, then no “breakdown” occurs in the corresponding risk-sensitive stochastic control problem, and thus relevant studies on existence and uniqueness of the solution to (3) have been done (cf. Nagai 1996, Bensoussan et al. 1998, and Bensoussan and Nagai 2000).

The LEQG problems were first investigated in Jacobson (1973), and then a theory of the LEQG control with complete or partial state information is developed in Whittle (1981) and Bensoussan and Schuppen (1985). Development of the studies of nonlinear risk-sensitive control can be seen in Bensoussan et al. (1998), Nagai (1996), Fleming and McEneaney (1995) etc.

Singular Limits and H^∞ Control

The large deviation theory of Freidlin-Wentzell applies to the risk-sensitive control problem with the criterion

$$\begin{aligned} J_\epsilon(x, 0; T) \\ = \frac{\epsilon}{\theta} \log E[e^{\frac{\theta}{\epsilon} \int_0^T \{\frac{1}{2} u_s^* S(X_s) u_s + V(X_s)\} ds}], \end{aligned} \quad (4)$$

$\epsilon > 0$, and the controlled dynamics

$$dX_t = \sqrt{\epsilon} \sigma(X_t) dB_t + \{b(X_t) + C(X_t)u_t\}dt. \quad (5)$$

The corresponding H-J-B equation is

$$\begin{cases} \frac{\partial v_\epsilon}{\partial t} + \frac{\epsilon}{2} \text{tr}[a(x)D^2v_\epsilon] + H_0(x, \nabla v_\epsilon) + V = 0 \\ v_\epsilon(T, x) = 0, \end{cases} \quad (6)$$

$$\begin{aligned} H_0(x, p) &= \frac{\theta}{2} p^* a(x) p + b(x)^* p \\ &\quad + \inf_{u \in R^m} \{u^* C(x) p + \frac{1}{2} u^* S(x) u\} \\ &= b(x)^* p - \frac{1}{2} p^* \left\{ C S^{-1} C(x)^* \right. \\ &\quad \left. - \theta a(x) \right\} p. \end{aligned}$$

By employing viscosity solution theory, we can see the solution v_ϵ of (6) converges to the viscosity solution v_0 of the equation

$$\begin{cases} \frac{\partial v_0}{\partial t} + H_0(x, \nabla v_0) + V = 0 \\ v_0(T, x) = 0. \end{cases} \quad (7)$$

when sending $\epsilon \rightarrow 0$. Noting that $H_0(x, p)$ can be regarded as

$$H_0(x, p) = b(x)^* p + \sup_z \{z^* p - \frac{1}{2\theta} z^* a(x)^{-1} z\} \\ + \inf_u \{u^* C(x) p + \frac{1}{2} u^* S(x) u\},$$

Eq. (7) is seen to be an H-J-Isaacs equation. Further, this equation has a unique viscosity solution under suitable conditions (Bensoussan and Nagai 1997), and it characterizes the lower value of the differential game with the criterion

$$I(0, T; z, u(z)) = \int_0^T \Psi(x_s, z_s, u(z)_s) ds, \\ \Psi(x, z, u) := -\frac{1}{2\theta} z^* a(x)^{-1} z \\ + \frac{1}{2} u^* S(x) u + V(x)$$

and the controlled dynamics

$$dx_s = \{b(x_s) + z_s + C(x_s)u(z)_s\}ds, \quad x_0 = x.$$

Here the sets $\mathcal{Z}_T$ and Γ_U of admissible strategies for z_s and $u(z)_s$ are, respectively, defined as follows. Let $\mathcal{Z}_T$ and $\mathcal{U}_T$ be, respectively, the totality of a measurable, R^N -valued (resp. R^m -valued) function on $[0, T]$ such that $\int_0^T |z_s|^2 ds < \infty$ (resp. $\int_0^T |u_s|^2 ds < \infty$). Then, for each $z \in \mathcal{Z}_T$ let $u(z)$ be a map defined on $\mathcal{Z}_T$ with its value on $\mathcal{U}_T$ such that whenever for each $0 \leq \tau \leq T$ and $z^{(1)}, z^{(2)} \in \mathcal{Z}$, $z^{(1)}(s) = z^{(2)}(s)$, almost everywhere on $0 \leq s \leq \tau$, then $u(z^{(1)})_s = u(z^{(2)})_s$, a.e. on $0 \leq s \leq \tau$. The set of such $u(z)$ is denoted by Γ_U . Thus, the lower value $\hat{v}_0^*$ of the game is defined as

$$\hat{v}_0^* = \inf_{u(z) \in \Gamma_U} \sup_{z \in \mathcal{Z}_T} I(0, T; z, u(z))$$

(cf. Elliott and Kalton (1972), Bensoussan and Nagai (1997) and references therein), and it is characterized by $v_0(0, x)$ with the unique

solution v_0 to (7). The differential game is known to be related to H^∞ or robust control. Function $V(x)$ is often assumed to be bounded from below but not from above, and $S(x)$ is to be positive definite. In that case, if θ is very large, then H-J-B equation (6) may fail to have a solution (cf. Bensoussan and Nagai 1997 and Bensoussan and Nagai 2000). The size of θ ensuring the existence of a solution to (6) is related to the level of robustness which the above differential game concerns (Basar and Bernhard 1991; Whittle 1990; Bensoussan et al. 1998; Bensoussan and Nagai 1997, 2000).

Risk-Sensitive Asset Management

The idea of risk-sensitive control applies to mathematical finance (Fleming 1995; Bielecki and Pliska 1999). Consider a market model with $m+1$ securities, where the security prices are governed by the ordinary and stochastic differential equations

$$dS^0(t) = r(X_t)S^0(t)dt, \quad S^0(0) = s^0,$$

$$dS^i(t) = S^i(t)\{\alpha^i(X_t)dt + \sum_{k=1}^N \sigma_k^i(X_t)dB_t^k\},$$

$$S^i(0) = s^i,$$

$i = 1, \dots, m$, with an N -dimensional Brownian motion process $B_t = (B_t^1, B_t^2, \dots, B_t^N)$ defined on a filtered probability space $(\Omega, \mathcal{F}, P; \mathcal{F}_t)$. The volatilities σ , the instantaneous mean returns α of the risky assets, and the interest rate r of the risk-less asset are affected by the economic factors $(X_t^1, \dots, X_t^n)$ defined as the solution of the stochastic differential equation

$$dX_t = \beta(X_t)dt + \lambda(X_t)dB_t, \quad X(0) = x \in R^n.$$

Let us set the total wealth W_T an investor possesses at time T to be $W_T = \sum_i N_T^i S_T^i$ with number of the share N_T^i invested to i -th security S_T^i . Expected power utility maximization maximizing $\frac{1}{\gamma} E[W_T^\gamma] = \frac{1}{\gamma} E[e^{\gamma \log W_T}]$, $\gamma < 1, \neq 0$ (Karatzas and Shreve 2010; Merton 1998) is equivalent to

$$\sup \frac{1}{\gamma} \log E[e^{\gamma \log W_T}], \quad (8)$$

and it has been studied in terms of “risk-sensitive asset management.” When introducing the portfolio proportion h_t^i invested to i -th security defined by $h^i(t) = \frac{N^i(t)S^i(t)}{W(t)}$ for each $i = 0, \dots, m$ and setting $h(t)^* = (h^1(t), h^2(t), \dots, h^m(t))$, $h^0(t) = 1 - \sum_{i=1}^m h^i(t)$, the total wealth W_t turns out to satisfy

$$\begin{aligned} \frac{dW(t)}{W(t)} &= \{r(X_t) + h(t)^* \hat{\alpha}(X_t)\} dt \\ &+ h(t)^* \sigma(X_t) dB_t, \end{aligned}$$

under the self-financing condition, where $\hat{\alpha}(x) = \alpha(x) - r(x)\mathbf{1}$, $\mathbf{1} = (1, 1, \dots, 1)^*$. Thus, W_t is considered to be a solution of the stochastic differential equation with a given initial wealth W_0 and a portfolio proportion $h(t)$ invested to the risky assets. In considering the maximization problem, the portfolio proportion h_t is considered an investment strategy to be controlled and assumed to be $\mathcal{G}_t^{S,X} := \sigma(S(u), X(u), u \leq t)$ progressively measurable in the case of full information. The problem is often considered under partial information where h_t is assumed to be $\mathcal{G}_t^S := \sigma(S(u), u \leq t)$ measurable. Here we first discuss the case of full information, and the set of admissible strategies $\mathcal{A}(T)$ (or $\mathcal{A}$) is determined as the totality of $\mathcal{G}_t^{S,X}$ progressively measurable investment strategies satisfying some suitably defined integrability conditions.

Considering (8) for $\gamma < 0$ amounts to studying the minimization problem

$$\hat{v}(0, x) = \inf_{h \in \mathcal{A}(T)} \log E[e^{\gamma \log W_T(h)}]. \quad (9)$$

Then introducing a probability measure p^h defined by

$$p^h(A) = E \left[e^{\gamma \int_0^T h_s^* \sigma(X_s) dW_s - \frac{\gamma^2}{2} \int_0^T h_s^* \sigma \sigma^*(X_s) h_s ds} : A \right],$$

$A \in \mathcal{F}_T$, the value function is expressed as

$$\begin{aligned} \hat{v}(0, x) &= \gamma \log W_0 \\ &+ \inf_{h \in \mathcal{A}(T)} \log E^h [e^{-\gamma \int_0^T \eta(X_s, h_s) ds}] \end{aligned}$$

with the initial wealth W_0 , where

$$\eta(x, h) = -h^* \hat{\alpha}(x) + \frac{1-\gamma}{2} h^* \sigma \sigma^*(x) h - r(x)$$

and $\hat{\alpha}(x) = \alpha(x) - r(x)\mathbf{1}$. By using the Brownian motion $B_t^h := B_t - \gamma \int_0^t \sigma^*(X_s) h_s ds$ under the new probability measure P^h , the dynamics of the economic factor X_t is written as

$$dX_t = \{\beta(X_t) + \gamma \lambda \sigma^*(X_t) h_t\} dt + \lambda(X_t) dB_t^h. \quad (10)$$

Thus, we arrive at the risk-sensitive control problem with the value function $\hat{v}(0, x)$ and the controlled dynamics X_t governed by (10). Note that $\frac{1-\gamma}{2} > 0$ for $\gamma < 1$ and that the case where $\gamma < 0$ is called risk averse, which we mainly discuss here. Then the corresponding H-J-B equation is deduced as

$$\begin{cases} \frac{\partial v}{\partial t} + \frac{1}{2} \text{tr}[\lambda \lambda^* D^2 v] + \frac{1}{2} (Dv)^* \lambda \lambda^* Dv \\ + \inf_h \{[\beta + \gamma \lambda \sigma^* h]^* Dv - \gamma \eta(x, h)\} = 0, \\ v(T, x) = \gamma \log W_0, \end{cases} \quad (11)$$

which can be rewritten as

$$\begin{cases} \frac{\partial v}{\partial t} + \frac{1}{2} \text{tr}[\lambda \lambda^* D^2 v] + \beta_\gamma^* Dv \\ + \frac{1}{2} (Dv)^* \lambda N_\gamma^{-1} \lambda^* Dv - U_\gamma = 0, \\ v(t, x) = \gamma \log W_0. \end{cases} \quad (12)$$

Here $U_\gamma = -\frac{\gamma}{2(1-\gamma)} \hat{\alpha}^* (\sigma \sigma^*)^{-1} \hat{\alpha} + r(x)$, $\beta_\gamma = \beta + \frac{\gamma}{1-\gamma} \lambda \sigma^* (\sigma \sigma^*)^{-1} \hat{\alpha}$ and $N_\gamma^{-1} = I + \frac{\gamma}{1-\gamma} \sigma^* (\sigma \sigma^*)^{-1} \sigma$. Under suitable conditions H-J-B equation (12) has a solution with sufficient regularities (Bensoussan et al. 1998; Nagai 2003). Moreover, identification

$$v(0, x; T) \equiv v(0, x) = \hat{v}(0, x) \quad (13)$$

can be verified. Further, an optimal investment strategy for problem (9) is given by $\hat{h}(t, X_t) = \frac{1}{1-\gamma} (\sigma \sigma^*)^{-1} \{\hat{\alpha}(X_t) + \sigma \lambda^* Dv(t, X_t)\}$ using solution $v(t, x)$ to (11) (Nagai 2003).

A typical example is the case of linear Gaussian model such that $r(x) = r$, $\alpha(x) = Ax + a$, $\sigma(x) = \Sigma$, $\beta(x) = Bx + b$, $\lambda(x) = \Lambda$, where A , B , Σ , Λ are constant matrices, a , b are constant vectors, and r is a constant. Then, the

solution to (12) has an explicit representation as $v(t, x) = \frac{1}{2}x^*P(t)x + q(t)^*x + k(t)$, where $P(t)$ is the negative semi-definite solution to Riccati equation

$$\begin{aligned} \dot{P}(t) + P(t)\Lambda N^{-1}\Lambda^*P(t) + K_1^*P(t) + P(t)K_1 \\ + \frac{\gamma}{1-\gamma}A^*(\Sigma\Sigma^*)^{-1}A = 0, \quad P(T) = 0 \end{aligned} \quad (14)$$

and $q(t)$, $k(t)$ are, respectively, the solutions to

$$\begin{aligned} \dot{q}(t) + (K_1 + \Lambda N^{-1}\Lambda P(t))^*q(t) + P(t)b \\ + \frac{\gamma}{1-\gamma}(A^* + P(t)\Lambda\Sigma^*)(\Sigma\Sigma^*)^{-1}\hat{a} = 0, \\ q(T) = 0 \end{aligned} \quad (15)$$

and

$$\begin{aligned} \dot{k}(t) + \frac{1}{2}\text{tr}[\Lambda\Lambda^*P(t)] + \frac{1}{2}q(t)^*\Lambda\Lambda^*q(t) \\ + \frac{\gamma}{2(1-\gamma)}(\hat{a} + \Sigma\Lambda^*q(t))^*(\Sigma\Sigma^*)^{-1} \\ (\hat{a} + \Sigma\Lambda^*q(t)) = 0, \quad k(T) = \gamma \log W_0, \end{aligned} \quad (16)$$

where $K_1 := B + \frac{\gamma}{1-\gamma}\Lambda\Sigma^*(\Sigma\Sigma^*)^{-1}A$, $\hat{a} = a - r\mathbf{1}$ and $N^{-1} := I + \frac{\gamma}{1-\gamma}\Sigma^*(\Sigma\Sigma^*)^{-1}\Sigma$. In this case the optimal strategy has a more explicit form: $\hat{h}_t = \frac{1}{1-\gamma}(\Sigma\Sigma^*)^{-1}[\hat{a} + AX_t] + \frac{1}{1-\gamma}(\Sigma\Sigma^*)^{-1}[\Sigma\Lambda^*q(t) + \Sigma\Lambda^*P(t)X_t]$ (cf. Kuroda and Nagai 2002 and Davis and Lleo 2008).

The economic factor X_t may be more suitably considered to be unobservable, and then the problem should be formulated as the risk-sensitive stochastic control problem under partial information. Indeed, one can formulate the problem by regarding the log prices $Y_t^i := \log S_t^i$, $i = 0, 1, 2, \dots, m$ as the observable quantities and the economic factor X_t as the unobservable system process. As for linear Gaussian models and hidden Markov models, the problems are reduced to be the ones of full information by obtaining the relevant controlled dynamics in a finite dimension through deducing the filtering

equation by the methods of change of measure (Nagai 1999; Nagai and Runggaldier 2008). Further, one can obtain the explicit form of the optimal strategy, which is $\mathcal{G}_t^S$ measurable, in the case of linear Gaussian model (Nagai 1999) as the parallel result to the above.

The case of $0 < \gamma < 1$ is called risk seeking, and problem (8) is equivalent to

$$\sup_h \log E[e^{\gamma \log W_T(h)}] \quad (17)$$

and its infinite time horizon counterpart is

$$\bar{\chi}(\gamma) = \sup_h \overline{\lim}_{T \rightarrow \infty} \frac{1}{T} \log E[e^{\gamma \log W_T(h)}]. \quad (18)$$

These problems for linear Gaussian models are extensively studied in Fleming and Sheu (1999, 2002). If $0 < \gamma$ is small, then there is a stationary solution of (14), and the verification theorem holds for the problem on infinite horizon (so does for the problem on a finite time horizon). Further, under some conditions there is a threshold $\bar{\gamma}$ such that $\bar{\chi}(\gamma) = \infty$ for $\bar{\gamma} < \gamma$. To know explicitly the size of $\bar{\gamma}$ is important, while it is limited to the case of 1 – dimension to be realized.

Problems on Infinite Horizon

The value for the problem on infinite time horizon counterpart of (9) is defined as

$$\hat{\chi}(\gamma) = \inf_{h \in \mathcal{A}} \lim_{T \rightarrow \infty} \frac{1}{T} \log E[e^{\gamma \log W_T(h)}], \quad (19)$$

when suitably setting the set $\mathcal{A}$ of admissible strategies. The corresponding H-J-B equation of ergodic type for the problem is seen to be

$$\begin{aligned} \chi(\gamma) = \frac{1}{2}\text{tr}[\lambda\lambda^*D^2w] + \beta_\gamma^*Dw \\ + \frac{1}{2}(Dw)^*\lambda N_\gamma^{-1}\lambda^*Dw - U_\gamma. \end{aligned} \quad (20)$$

However, when setting as $\mathcal{A} = \{h_{\cdot|[0,T]} \in \mathcal{A}(T), \quad \forall T\}$, identification of $\hat{\chi}(\gamma)$ with the solution $\chi(\gamma)$ to the H-J-B equation (20) cannot

be seen in general. Indeed, even in the case of linear Gaussian model, such identification does not always hold (Fleming and Sheu 1999; Kuroda and Nagai 2002; Nagai 2003) if $\gamma < 0$. Instead, introduce the asymptotic value

$$\tilde{\chi}(\gamma) = \lim_{T \rightarrow \infty} \frac{1}{T} \inf_{h \in \mathcal{A}(T)} \log E[e^{\gamma \log W_T(h)}].$$

Then we can see that $\chi(\gamma) = \tilde{\chi}(\gamma)$ under sufficiently general conditions (cf. Hata et al. 2010 and Nagai 2012). Since verification (13) in the case of a finite time horizon is seen under fairly general conditions, we can obtain asymptotically optimal strategy for $\tilde{\chi}(\gamma)$. Further, if the solution $w(x)$ to (20) satisfies

$$(\nabla w)^* \lambda N_\gamma^{-1} \lambda^* \nabla w(x) - \hat{\alpha}^*(\sigma \sigma^*)^{-1} \hat{\alpha}(x) \rightarrow -\infty \quad (21)$$

as $|x| \rightarrow \infty$, then we can see $\hat{\chi}(\gamma) = \tilde{\chi}(\gamma)$, and an optimal strategy for (19) is given by $\tilde{h}(X_t) := \frac{1}{1-\gamma}(\sigma \sigma^*)^{-1} \{\hat{\alpha}(X_t) + \sigma \lambda^* \nabla w(X_t)\}$ (Nagai 2012).

In the case of linear Gaussian model, the solution to the H-J-B equation of ergodic type is given by $w(x) = \frac{1}{2} x^* \bar{P} x + \bar{q}^* x$ with the stationary solutions $\bar{P}$ of (14) and $\bar{q}$ of (15), and if

$$\bar{P} \lambda \Sigma^* (\Sigma \Sigma^*)^{-1} \Sigma \Lambda^* \bar{P} < A^* (\Sigma \Sigma^*)^{-1} A$$

holds, then one can see that $\chi(\gamma) = \hat{\chi}(\gamma)$ (Kuroda and Nagai 2002). Further, the optimal strategy is given by $\hat{h}_t = \hat{h}(X_t)$, with $\hat{h}(x) = \frac{1}{1-\gamma}(\Sigma \Sigma^*)^{-1} [\hat{\alpha} + \Sigma \Lambda^* \bar{q} + (A + \Sigma \Lambda^* \bar{P})x]$ (Kuroda and Nagai 2002). Decomposition as $\hat{h}_t = \frac{1}{1-\gamma} \hat{h}_t^1 + \frac{\gamma}{1-\gamma} \hat{h}_t^2 := \frac{1}{1-\gamma}(\Sigma \Sigma^*)^{-1} [\hat{\alpha} + A X_t] + \frac{\gamma}{1-\gamma}(\Sigma \Sigma^*)^{-1} [\Sigma \Lambda^* \bar{q} + \Sigma \Lambda^* \bar{P} X_t]$, $\bar{P} = \frac{1}{\gamma} \bar{P}$, $\bar{q} = \frac{1}{\gamma} \bar{q}$ is regarded as a generalization of Merton's mutual fund theorem (Davis and Lleo 2008; Merton 1998). Here $\hat{h}_t^1$ is a log utility portfolio (Kelly portfolio) (Kelly 1956). While, the partial information counterpart of Kuroda and Nagai (2002) was discussed in Nagai and Peng (2002) and the corresponding results are obtained.

Risk-sensitive investment management in the models admitting jumps in asset prices and also factor processes is studied by Davis and Lleo (cf. Davis and Lleo (2015) and references there in). They also consider the case when a benchmark is involved in the asset management.

In relation to the above problems on mathematical finance, a new kind of problem studying

$$I(\kappa) = \lim_{T \rightarrow \infty} \frac{1}{T} \inf_{h \in \mathcal{A}(T)} \log P(\log W_T(h) \leq \kappa T) \quad (22)$$

for a given constant κ arises, and it is called “downside risk minimization.” The problem is considered “large deviation control” and can be discussed as the dual to risk-sensitive asset management (19) in the risk-averse case $\gamma < 0$ (Hata et al. 2010; Nagai 2012, 2011). Indeed, we obtain

$$I(\kappa) = - \inf_{k \in (-\infty, \kappa]} \sup_{\gamma < 0} \{\gamma k - \hat{\chi}(\gamma)\}.$$

Further, an asymptotically optimal strategy is given as follows. For given κ , take $\gamma(\kappa)$ which attains the supremum in $\sup_{\gamma < 0} \{\gamma \kappa - \hat{\chi}(\gamma)\}$, then the optimal strategy $\hat{h}(t, X_t)$, $0 \leq t \leq T$ for problem (9) with $\gamma = \gamma(\kappa)$ forms the asymptotically optimal strategy for (22). If the solution $w(x)$ to (20) with $\gamma = \gamma(\kappa)$ satisfies (21), then

$$J(\kappa) := \inf_{h \in \mathcal{A}} \lim_{T \rightarrow \infty} \frac{1}{T} \log P(\log W_T(h) \leq \kappa T)$$

holds and $\tilde{h}(X_t) := \frac{1}{1-\gamma}(\sigma \sigma^*)^{-1} \{\hat{\alpha}(X_t) + \sigma \lambda^* \nabla w(X_t)\}$ forms an optimal strategy for $J(\kappa)$ (Nagai 2012).

Historically, the studies of “upside maximization” concerning

$$\bar{I}(\kappa) = \sup_{h \in \mathcal{A}} \lim_{T \rightarrow \infty} \frac{1}{T} \log P(\log W_T(h) \geq \kappa T)$$

have been preceding (cf. Pham 2003), and the duality relationship between this and (18) was discussed under restrictive conditions. To develop further studies for the problem, there are difficulties to know the size of threshold $\bar{\gamma}$, which is

mentioned at the end of section “[Risk-Sensitive Asset Management](#)”.

Abstract

Given a grasping system composed by a robotic hand and a grasped object, the aim of *grasp control* is to make the object follow a certain desired trajectory while preserving

the contact. In this essay, after a concise explanation of the mathematical model of a grasping system, with a particular focus on the contact constraints, a computed-torque controller that guarantees trajectory tracking and grasp maintenance is described. Last sections contain suggestions for further reading and information about open research challenges in the field of grasp control.

Keywords

Multifingered robotic hands · Grasping · Dexterous manipulation

Introduction

Grasp control refers to the art of controlling the motion of an object by constraining its dynamics through contacts with a hand. The process of controlling the grasp is not limited to robotic hands only, but also applies to human hands (Johansson and Edin 1991) and to all other mechanisms using contact constraints to control the motion of the manipulated object (Brost and Goldberg 1996).

A crucial role in control of grasping is played by contact constraints. All the interactions between the robotic hand and the grasped object occur at the contacts whose understanding is paramount (Salisbury and Roth 1983).

The unilateral nature of contact interaction in grasping makes the control problems much more challenging than cooperative manipulation where multiple arms hold the object rigidly allowing bilateral force transmission at each contact point (Chiacchio et al. 1991).

The importance of unilateral contact constraints in grasping led large part of the literature to focus on the closure properties of the grasp (Bicchi 1995). Those properties refer to the ability of a grasp to prevent motions of the grasped object relying only on unilateral frictionless constraints in case of form closure (Reuleaux 1876) and on contact constraints with friction in case of force closure (Nguyen 1988). While form closure is a purely geometric property of the grasp and depends on where the unilateral

contact points are on the object, force closure depends on the ability that the robotic hand has to resist and apply forces to the object through the contacts while satisfying the friction constraints. In other terms, force closure directly involves the control of the robotic hand kinematics and not only the geometry of the contacts (Bicchi 1995). This essay focuses on force-closed grasps.

The optimal choice of the contact points on the object surface is a critical issue known as grasp planning. Among the many optimal criteria that have been proposed in the literature to choose the contact points, we recall the one proposed in Ferrari and Canny (1992) where the grasping configuration is evaluated according to the magnitude of the largest worst-case disturbance wrench that can be resisted by the grasp.

Many approaches have been studied in the literature on grasp planning in presence of uncertainties. The uncertainty can be either due to the shape of the object which is partially known or partially sensed as in Goldfeder et al. (2009) or due to the errors in positioning the fingers on the object during the grasping (Roa and Suarez 2009). In what follows all the parameters of the grasp, including those related to the hand, the object and the contact points are assumed to be known with no uncertainties.

The main objective of grasp control is that of tracking a desired trajectory with the grasped object by applying a set of contact forces satisfying the friction constraints (Bicchi and Kumar 2000). Complex in-hand object motions can be obtained by rolling and sliding the contact points on the object surface as proposed in Montana (1988) or by using finger gaiting to get large-scale motions (Han and Trinkle 1998). This essay deals with non-rolling and non-sliding contact points and summarizes the fundamental theory of computed-torque control for object trajectory and internal force control proposed in Li et al. (1989).

For a comprehensive review of the theory of grasping and its control, the reader is referred to Murray et al. (1994), Shimoga et al. (1996), Okamura et al. (2000), Bicchi and Kumar (2000), and Prattichizzo and Trinkle (2016).

Grasp Modeling and Control

Contact and Grasp Model

Notations and definitions on grasping are taken from Prattichizzo and Trinkle (2016). Refer to Fig. 1 and let $\{N\}$ represent the inertial frame fixed to the palm of the robotic hand. Let $u = [p^T, \phi^T]^T \in \mathbb{R}^6$ denote the vector describing the position and orientation of frame $\{B\}$, fixed to the object, relative to $\{N\}$. Vector ϕ expresses the Euler angles, the pitch-roll-yaw variables, or the exponential coordinates parameterizing $SO(3)$. Denote by $v = [v^T \omega^T]^T \in \mathbb{R}^6$, the twist of the object. It is worth to note that v is not equal to $\dot{u}$, but satisfies $v = U(u)\dot{u}$ where matrix $U \in \mathbb{R}^{6 \times 6}$ is such that UU^T is the identity matrix, and the dot over the variable implies differentiation with respect to time (Murray et al. 1994). The joint variables of the robotic hand are defined by $q = [q_1 \cdots q_{n_q}]^T \in \mathbb{R}^{n_q}$. Let n_c be the number of contact points. The position of contact point i in $\{N\}$ is defined by the vector $c_i \in \mathbb{R}^3$, in the contact point frame $\{C\}_i$ whose axes are $\{\hat{n}_i, \hat{t}_i, \hat{f}_i\}$ where the unit vector $\hat{n}_i$ is normal to the tangent plane at the contact, and directed toward the object while the other two unit vectors are orthogonal and lie in the tangent plane.

Two matrices are of utmost importance in grasp analysis: the *grasp matrix* G and the *hand Jacobian* J . These two matrices are computed using the complete grasp matrix, the complete Jacobian and the contact selection matrix that are defined as follows: the transpose of the *complete grasp matrix* $\tilde{G}^T \in \mathbb{R}^{6n_c \times 6}$ maps the object twist to the n_c twist vectors of the contact frames $\{C\}_i$ as thought on the object: $v_{c,obj} = \tilde{G}^T v$ while the *complete hand Jacobian Matrix* $\tilde{J} \in \mathbb{R}^{6n_c \times n_q}$ maps the joint velocities to the twists of the contact frames as thought on the hand: $v_{c,hnd} = \tilde{J}\dot{q}$.

When a contact occurs between the hand and the object, assuming no sliding, some components of the relative contact twist between the object and the hand are set to zero according to the used contact model. In this essay the *hard-finger* (HF) and the *soft-finger* (SF) contact models are considered (Mason and Salisbury 1985). Those components are selected by the *contact selection matrix* which selects m components of the relative contact twists for all the contacts and sets them to zero: $H(v_{c,hnd} - v_{c,obj}) = 0$. For more details on how to compute the contact selection matrix, the reader is referred to Prattichizzo and Trinkle

Robot Grasp Control,

Fig. 1 A two-fingered hand grasping an object

(2016). Then the following contact constraint equation is obtained:

$$\begin{bmatrix} J & -G^T \end{bmatrix} \begin{bmatrix} \dot{q} \\ v \end{bmatrix} = 0 \quad (1)$$

where the transpose of the grasp matrix and the hand Jacobian are defined by multiplying the contact selection matrix and the transpose of the complete grasp matrix and the complete hand Jacobian as

$$G^T = H\tilde{G}^T \in \mathbb{R}^{m \times 6}$$

$$J = H\tilde{J} \in \mathbb{R}^{m \times n_q}$$

In the force domain, the wrenches that the hand applies to the object at the contact points are collected in the vector λ . Correspondingly, on the hand, a force vector $-\lambda$, opposite to the preceding one, is applied by the object through the contact points. At each contact point, the contact wrenches have components only along the directions constrained by the contact model. Furthermore, contact force components must satisfy the friction constraints (see section “[Force Closure and Grasp Control](#)”). More specifically, the m -dimensional vector $\lambda = [\lambda_1^T \cdots \lambda_{n_c}^T]^T$ contains the contact wrenches components applied to the object through the n_c contacts, where the wrench at contact i is defined, for the different contact models here considered, as $\lambda_i = [f_{in} \ f_{it} \ f_{io}]^T$ for the HF contact model and $\lambda_i = [f_{in} \ f_{it} \ f_{io} \ m_{in}]^T$ for the SF contact model. The subscripts indicate one normal (n) and two tangential (t,o) components of contact force f_i and moment m_i at contact i .

In terms of forces, the grasp matrix maps the transmitted contact wrenches λ to the set of wrenches that the hand can apply to the object $G\lambda$, and the transpose of hand Jacobian maps the contact forces $-\lambda$ to the corresponding vector of joint loads $-J^T\lambda$.

Grouping all the non-contact wrenches applied to the object in $g \in \mathbb{R}^6$ and all the non-contact contributions to the joint loads of the robotic hand in $\tau \in \mathbb{R}^{n_q}$, rigid body dynamic equations of the whole system, consisting of hand and of the grasped object, are

$$M_{\text{obj}}(u)\dot{v} + N_{\text{obj}}(u, v) = G\lambda + g$$

$$M_{\text{hnd}}(q)\ddot{q} + N_{\text{hnd}}(q, \dot{q}) = -J^T\lambda + \tau$$

where $M_{\text{obj}}(\cdot)$ and $M_{\text{hnd}}(\cdot)$ are symmetric, positive definite inertia matrices and $N_{\text{obj}}(\cdot, \cdot)$ and $N_{\text{hnd}}(\cdot, \cdot)$ are the velocity-product terms for the object and the hand, respectively. For the sake of simplicity, the gravity terms are disregarded.

The dynamics of the hand and object are not independent but depend on the kinematic constraints imposed by the contact model (1):

$$\begin{bmatrix} -G \\ J^T \end{bmatrix} \lambda = \begin{bmatrix} \bar{g} \\ \bar{\tau} \end{bmatrix} \quad (2)$$

subject to $J\dot{q} = G^Tv$

where

$$\bar{g} = g - M_{\text{obj}}(u)\dot{v} - N_{\text{obj}}(u, v).$$

$$\bar{\tau} = \tau - M_{\text{hnd}}(q)\ddot{q} - N_{\text{hnd}}(q, \dot{q})$$

It is worth underlying that dynamics can be disregarded for slow motions of the hand and of the object while it becomes very relevant in applications with high-speed grasping and manipulation as discussed in Namiki et al. (2003).

Controllable Wrenches and Twists

From the first equation in (2) to impose any motion to the object by contact forces, the grasp matrix G must be full row rank, i.e., $\text{rank}(G) = 6$ which is equivalent to have a trivial null space of G^T , i.e., $\mathcal{N}(G^T) = 0$. This is an important property of the grasp which has been referred to as *non-indeterminate* in Prattichizzo and Trinkle (2016) to reflect the idea that the contacts on the object are placed in a way that there are no twists of the object that are not controllable by contact wrenches.

However, this condition depends only on the contacts on the object and does not consider the role of the hand kinematics which comes from the second equation in (2) and from the contact constraint. Under the simplifying assumption that $\mathcal{N}(J^T) = 0$, referred to as *non-defective* grasp in Prattichizzo and Trinkle (2016), it is simple

to verify that, for any given contact wrench λ , a control torque τ exists which is able to apply the given contact wrench. The mechanical interpretation of this assumption is that when $\mathcal{N}(J^T) = 0$, there are no contact forces resisted by the robotic hand constraints, i.e., with zero joint load. The simplifying assumption of non-defective grasps ensures that $\mathcal{N}(J^T) \cap \mathcal{N}(G) = 0$ which is a necessary condition to determine the contact force λ from the rigid body equation (2) as shown in Prattichizzo and Trinkle (2016).

If a grasp is non-defective, it means that each finger of the robotic hand involved in the contact with the object must have a number of joints sufficient to control all the components of the contact wrench. For example, in case of two HF contact points occurring at the fingertips of a two-fingered robotic hand, each finger must have at least three joints and must be in a non-singular configuration.

This essay does not consider whole hand or power grasps which, differently from the fingertip grasps, exploit the whole surface of the fingers, including the palm, to constraint the object. The analysis of controllable wrenches and twists for whole-arm grasps, taking into account the hand and object dynamics, can be found in Prattichizzo and Bicchi (1997).

Force Closure and Grasp Control

The dynamic formulation of the grasp with the contact kinematic constraints given in (2) holds only if the contact forces satisfy the friction law imposing constraints on the components of the contact force and moment. Limiting the analysis to HF contact models, Coulomb friction law requires that the components of contact force λ_i at the i -th contact lie inside the friction cone $\mathcal{F}_i$:

$$\mathcal{F}_i = \{(f_{in}, f_{it}, f_{io}) \mid \sqrt{f_{it}^2 + f_{io}^2} \leq \mu_i f_{in}\} \quad (3)$$

where μ_i represents the friction coefficient at the i -th contact. Extending to all contact points, λ is constrained to lie in $\mathcal{F}$ where $\mathcal{F}$ is the generalized friction cone defined as $\mathcal{F} = \mathcal{F}_1 \times \dots \times \mathcal{F}_{n_c} = \{\lambda \in \mathbb{R}^m \mid \lambda_i \in \mathcal{F}_i; i = 1, \dots, n_c\}$.

While grasping an object, the applied contact forces must be consistent with the friction constraints. This is not straightforward for the grasp control and requires to exploit the beneficial characteristics of the internal forces. From the object dynamics in (2), for a given $\bar{g}$ one gets

$$\lambda = -G^+ \bar{g} + N(G) \gamma \quad (4)$$

where G^+ denotes the generalized inverse of the grasp matrix and $N(G)$ denotes a matrix whose columns form a basis for $\mathcal{N}(G)$ and γ is a vector parameterizing the solution set. The contact force λ consists of a particular solution balancing the $\bar{g}$ term and of a homogeneous solution belonging to the null space of the grasp matrix.

In general, the particular solution $-G^+ \bar{g}$ does not satisfy the friction constraint (3) at all the contact points and needs the homogeneous solution $\lambda_h = N(G) \gamma$ to keep the contact forces within the friction cones. Contact forces λ_h in $\mathcal{N}(G)$ are referred to as *internal forces* since they do not contribute to the object dynamics, i.e., $G \lambda_h = 0$. Instead, these forces affect the tightness of the grasp and play a crucial role in maintaining grasps that rely on friction. The existence of a nontrivial null space of the grasp matrix is a desirable property and has been referred to as *graspability* (Prattichizzo and Trinkle 2016).

Another relevant and desirable property of the grasp is the *frictional force closure* which means that for any non-contact wrench $\bar{g}$, an internal force λ_h exists such that the contact force λ in (4) belongs to the generalized friction cone $\mathcal{F}$. In Murray et al. (1994), authors state that a grasp has frictional form closure if and only if the grasp matrix is full row rank (non-indeterminate grasp) and there exists λ_h such that $G \lambda_h = 0$ and λ_h belongs to the interior of the generalized friction cone $\mathcal{F}$.

Grasp control is about using contact forces, which must satisfy the friction constraints, to let the object track a given trajectory. This is also referred to as dexterous manipulation (Bicchi and Kumar 2000). In Li et al. (1989), a computed-torque controller is proposed to track both the

desired trajectory of the grasped object u_{des} and the desired internal force $\lambda_{h,\text{des}}$. Under the additional simplifying assumption that the robotic hand Jacobian is invertible, i.e., there are no redundant motions of the fingers, the computed-torque control law

$$\begin{aligned}\tau = & N_{\text{hnd}}(q, \dot{q}) + J^T G^+ N_{\text{obj}}(u, v) \\ & - M_{\text{hnd}} J(q) J^{-1} \dot{J} \dot{q} + M_{\text{ho}} \dot{U} \dot{u} + \\ & + M_{\text{ho}} U (\ddot{u}_{\text{des}} - K_v \dot{e}_u - K_u e_u) \\ & + J^T (\lambda_{h,\text{des}} - K_s \int e_{\lambda_h}),\end{aligned}$$

with $M_{\text{ho}} = M_{\text{hnd}} J(q) J^{-1} G^T + J^T G^+ M_{\text{obj}} J$, guarantees that both the trajectory and the internal force errors

$$\begin{aligned}e_u &= u - u_{\text{des}} \\ e_{\lambda_h} &= \lambda_h - \lambda_{h,\text{des}}\end{aligned}$$

with respect to the desired object trajectory u_{des} and internal force $\lambda_{h,\text{des}}$, converge to zero according to a second- and first-order dynamics, respectively.

$$\begin{aligned}\ddot{e}_u + K_v \dot{e}_u + K_u e_u &= 0 \\ e_{\lambda_h} + K_s \int e_{\lambda_h} &= 0\end{aligned}$$

where K_v , K_u , and K_s are positive definite matrices.

The computed-torque controller proposed in Li et al. (1989) guarantees only that the desired object trajectory and the desired internal forces are asymptotically tracked, but it does not ensure the non-violation of friction constraints by the contact forces. To guarantee that the contact force vectors remain in the friction cone during the manipulation, a force distribution problem must be solved at each time instant. The force closure assumption ensures that a solution exists that satisfies the friction constraints during the manipulation. This solution, which becomes the reference for the internal force control, can be found with an efficient algorithm, based on the minimization of a convex function, that

checks the force closure property at each time instant (Bicchi 1995).

Summary and Future Directions

The basic foundation of grasp control has been reviewed with a particular attention to modeling of contact constraints, force closure, and control of object motion and internal forces. This essay did not explicitly address grasp stability that is often equated to grasp closure, because all external forces can be balanced by the hand. A more formal analysis of grasp stability in terms of deflection from an equilibrium point has been proposed for robotic hands with general kinematics in Jen et al. (1996).

The computed-torque control is a classical approach to the grasp control. For a deeper study of other approaches to grasp control based on passivity theory, the reader is referred to Wimboeck et al. (2011).

Developments in underactuated robotic hands (Birglen et al. 2008) have led to a renewed interest in grasp control. Designing hands with a lower number of actuators has a lot of advantages in terms of robustness and reliability, but dramatically reduces the dexterous manipulation abilities which can be recovered only by devising new control algorithms or innovative designs (Odhner and Dollar 2011; Prattichizzo et al. 2013; Santina et al. 2015).

Together with underactuation, *softness* has become an important design feature of robotic hands (Catalano et al. 2014; Deimel and Brock 2016). Endowing multifingered hands with passive compliance enhances adaptability, robustness, and safety and allows new grasp planning strategies based on *environmental constraints exploitation* (Brock et al. 2016). Grasping with soft hands was not explicitly addressed by this essay because such devices are mainly used to perform power grasps (Pozzi et al. 2017). Thus, instead of building a precise model of the hand structure and finely control the grasp, usually the focus is put on the control of the robot arm and on the closing capabilities of the used robotic hand, so to well align it to the grasped object (Pozzi et al. 2018).

Cross-References

Grasp control deals with control of contact forces and motion of the grasped object. The reader can refer to the essays on ► [“Robot Motion Control”](#) and ► [“Force Control in Robotics”](#) of this Encyclopedia to study the subjects in more depth. It is worth highlighting that the control of grasping shares some aspects of problem formalization and methods with parallel robots. An essay on ► [“Parallel Robots”](#) is included in this Encyclopedia.

The essay on ► [“Robot Visual Control”](#) is important for readers interested to study the problem of grasp control with vision sensing. The use of cameras is very common in robotic grasping. If you think of how humans grasp objects, it is natural to think about grasping supported by vision especially during the reaching phase before grasping the object.

The last cross-reference is with the essay on ► [“Walking Robots”](#). During a manipulation task, it can happen that the robot needs to change the contact points to hold the object in another configuration. This is obtained moving the fingers to establish new contact points with the object. In the literature this is referred to as finger gaiting and shares common problems with the problem of walking robots.

Recommended Reading

Grasp synthesis and dexterous manipulation are important research topics. Grasp synthesis is the problem of choosing the posture of the hand and contact point locations to optimize a grasp quality metric. One of the first studies of grasp synthesis for multi-fingered hands was undertaken in Jameson (1985) where the author proposed a Levenberg-Marquardt algorithm to search the surface of an object for the locations of three points that would achieve force closure. Since this work, many other metrics and approaches to searching for high-quality grasps have been implemented as discussed in Nguyen (1988), Park and Starr (1992), Chen and Burdick (1993), Pollard (1997), Pozzi et al. (2017), and therein references. A new trend is to tackle grasp

synthesis with approaches based on machine learning techniques. There are methods based on deep learning, for example, that take as input a RGBD image or point cloud of the object and output an estimate of the best grasp pose that can be performed, without assuming a known 3D model of the object (Mahler et al. 2017; ten Pas et al. 2017). These algorithms achieve impressive success rates, but for the moment are mainly applied to simple two-fingered grippers.

Dexterous manipulation is the capability of manipulating an object so as to arbitrarily steer its configuration in space. Research on dexterous manipulation first appeared in Hanafusa and Asada (1979) where the authors developed a plan to turn a nut onto a bolt. Since then a progression of increasingly complex manipulation tasks has been studied to varying degrees of detail. For the planar case, the reader is referred to Mason (1982), Brost (1991), Peshkin and Sanderson (1988), Lynch (1996) and therein references, whereas for the three dimensional case, several interesting approaches have been proposed (Cherif and Gupta 1999; Han et al. 2000; Higashimori et al. 2007). More recently, for example, kinematic trajectory optimization and bio-inspired methods have been applied for planning and executing dexterous manipulation tasks with fully actuated, torque-controlled hands (Sundaralingam and Hermans 2017; Ruiz Garate et al. 2018).

Dexterous manipulation can be evaluated with manipulability ellipsoids of velocity and force as proposed in Chiacchio et al. (1991) for multiple-fingered systems and more recently in Prattichizzo et al. (2012) for underactuated robotic hands.

Authors recently created video lectures on grasp control that are freely available on YouTube (<http://sirslab.dii.unisi.it/GraspingCourse/index.html>) (Pozzi et al. 2019).

Robot Learning

Jens Kober

Cognitive Robotics Department, Delft University of Technology, Delft, The Netherlands

Abstract

With increasingly complex robot hardware and the push to enable robots to work in unstructured environments, there has been an increasing interest in applying machine learning and artificial intelligence techniques to systems and control problems in robotics. At the same time, many machine learning approaches have been developed with robotic problems as motivating use cases. Robot learning spans the problems of learning models, sensing, acting, as well as integrated approaches and has been applied to many types of robot embodiments. The algorithms cover most fields of machine learning. However, due to the specific challenges in robotics, these either need to be adapted or new approaches have to be developed.

Keywords

Supervised learning · Unsupervised learning · Reinforcement learning · End-to-end learning · Model learning

Introduction

Robot learning, as the name indicates, is the application of machine learning and artificial intelligence methods to robotic problems. Hence the field of robot learning is almost as broad as robotics itself, and applications range from the optimization of mechanical designs, over perception, high-level decision-making, and planning, to low-level control on all different kinds of robots like autonomous vehicles, drones, legged robots, or robot arms, on their own or in multi-robot settings, potentially also including interactions with humans.

Recently, there has been tremendous progress in the field of machine learning, in particular due to the availability of big data and the drastically increased computational power. The progress in deep learning has enabled many new applications, often outperforming classical, hand-designed approaches to an extent that those older methods have been largely superseded by learning-based methods. For example, image recognition, speech recognition, automated translations, text to speech, recommender systems, or text mining frequently are AI-based and widely deployed online and in smartphone apps. All these components are invaluable to build a complete robot that can naturally interact with human users and its environment. Here we will not focus on such components but rather on approaches that are closer to systems and control: namely, low-level and high-level control and planning, perception and sensor fusion, as well as models of the robot and its environment. Robot learning in this setting has close ties both to computer science and systems and control, in particular to optimal control, adaptive control, and system identification. In this article we will first discuss different types of machine learning, then outline different application areas of robot learning, and finally discuss the particular challenges of robot learning.

Types of Learning

In machine learning, different types of learning need to be distinguished: supervised learning, unsupervised learning, and reinforcement learning. Those approaches differ in what kind of data is available to the learning algorithm and in what it is supposed to learn from that data. Application areas will be discussed in the next section.

Supervised Learning

In supervised learning we assume that the learner has access to samples of input-output combinations. The task of the learner is to reproduce and to generalize this mapping, i.e., it also needs to interpolate between and to extrapolate from the samples. The tricky part here is to find a good,

compact representation of the mapping that only models the relevant parts and not unnecessary details like noise. The optimization criterion is hence a combination of fitting the observed data, predicting unobserved data well (which is in practice achieved by holding out a part of the dataset), and encouraging simple models (regularization). Supervised learning has close ties to system identification. Within supervised learning, there is an additional subdivision in classification and regression. In classification we have a fixed, finite set of labels (or their probability) that need to be predicted. In regression the learned system acts like a function with continuous outputs. Machine learning typically assumes independent and identically distributed samples, while data selection in robotics can be a major challenge.

Unsupervised Learning

In unsupervised learning the learner only has access to input data. The task is to discover structures in the data which enable lower-dimensional representations. Typical applications are clustering, where data needs to be grouped into several clusters with similar properties, and generative models, where the aim is to learn models that generate “fake” data that is distributed as similar as possible to the real data.

Reinforcement Learning

Reinforcement learning does not operate on a fixed dataset but rather learns the optimal mapping from inputs to outputs through interactions with the system. This mapping is a controller, called policy, mapping from states to optimal actions. The agent receives a reward, i.e., a scalar value that tells it how well it did, in every step, and its goal is to optimize for the cumulative (potentially discounted) reward, called the return. In contrast to optimal control, typically rewards are considered instead of costs, which do not necessarily need to conform to a particular form. Furthermore, reinforcement learning usually considers the underlying system dynamics and reward functions to be unknown, and the agent hence needs to implicitly learn them as well through interactions with the

system. Reinforcement learning approaches can be largely classified into model-based methods that first learn a model and then apply optimal control methods to derive the policy and model-free methods that directly learn a policy or a value function, i.e., the desirability of each state.

Combinations

As already alluded, the distinction between these types of learning is not that clear-cut, and combining them can be very beneficial. Semi-supervised learning describes the case in between supervised and unsupervised learning, i.e., where only some of the data points are labeled and the labels of the other points need to be inferred from the structure of the data. Reinforcement learning can employ models that have been learned via supervised learning, or can be initialized with policies learned by supervised learning, that are then further refined. Active learning denotes approaches where the agent does not operate on a fixed dataset but has the option to actively query for more data, e.g., for labels of inputs that it is unsure about.

Scope of Learning

In robot learning the big question is always “What parts of the system do we learn?”. Traditionally, learning approaches have been applied to one or several components in an overall system, usually the ones that are hard to design in a traditional manner. In a control system, these components could, for instance, replace an observer, a system model, or a controller. With the advent of deep learning, end-to-end learning has become possible, i.e., learning the complete mapping from raw, high-dimensional sensor inputs to control actions. The former approach integrates well with traditional system design approaches and makes optimal use of existing knowledge; the latter enables applications that were previously infeasible and potentially results in better overall performance, removing bottlenecks of specific components.

Components

In robotics, we traditionally distinguish components for sensing and acting. A third category are models of the system and environment that can be used both in sensing and acting.

Models

Here models of the environment and/or the system are learned. This ranges from learning models of the dynamics of the robot and subsequently using those in an inverse-dynamics control scheme to learning prediction models of human behavior that then can be used to plan collision-free movements. For a detailed overview, see Nguyen Tuong and Peters (2011). A large part of the work in this domain falls into the domain of supervised learning, where both the inputs and outputs of the robot system or parts of the environment are observed and the learning agent tries to fit a model that best explains and reproduces the observed behaviors. Similar to system identification, gray box models or black box models can be learned. In gray box models, the structure of the model is known from insights into how the system behaves and only parameter values need to be fitted. In black box models, we either assume a very generic parametrization or apply nonparametric models. Depending on the intended application, different types of models are learned: forward models or inverse models. A forward model predicts the next state, given the current state and the taken action. A forward model can be used for model-based controller design or simply as a component to predict the outcome of an action. Examples include using learned models of the system in optimal control, e.g., via iLQG, or in planning frameworks where they are used for predictions that are hard to model analytically, in a model-based filter for perception, or to replace components that are too time-consuming to solve analytically in every time-step. Also see an example in Fig. 1. Inverse models predict which action needs to be taken given a current state and a desired next state. Inverse models can hence be employed more directly in model-based control. In many cases an inverse model is not unique or an ill-posed problem. Learning

Robot Learning, Fig. 1

An example for learning models: the learned model is subsequently employed to learn inverted helicopter flight. (Source (Ng et al. 2006) with permission of Andrew Ng)

a forward and an inverse model simultaneously, called a mixed-model, can often be helpful to learn consistent models. Popular methods include linear regression, support vector regression, locally weighted projection regression, Gaussian mixture models, Gaussian processes, and (deep) neural networks.

Rather than learning models in a supervised fashion, there are also many approaches that learn generative models, which is a form of unsupervised learning. See Bengio et al. (2013) for a more extensive survey. Internally such generative models learn structures that form compact representations of the system. While the training of such generative models is often a form of supervised learning, i.e., minimizing the distance between real and fake data, the final result corresponds to unsupervised learning. Popular approaches here include hidden Markov models, Gaussian mixture models, variational autoencoders, and generative adversarial networks. A related problem is learning latent representations or state representations, i.e., a mapping from observation, which are high-dimensional inputs, to a state, which is a compact representation that is sufficient to describe the behavior of the system. Many learning approaches based on neural networks implicitly learn such state representations through imposed restrictions, e.g., deeper layers with limited size. When learning state representations explicitly, one of the most prominent criteria is autoencoding, i.e., being able to reconstruct the original input from the compact

state, but can also include additional criteria like predicting the next state or rewards. For an extensive survey see (Lesort et al. 2018).

Sensing

A robot relies on sensors to perceive and understand its own state and the state of its environment. For extensive surveys, see Sünderhauf et al. (2018), Schwarting et al. (2018), Premebida et al. (2018) and Ruiz-del Solar et al. (2018). While some sensors, like joint encoders, deliver usable information almost directly, other sensors (e.g., like conventional cameras, time-of-flight cameras, LiDAR, radar, tactile arrays, or microphones) deliver high-dimensional inputs that first need to be processed before control decisions can be taken. Applications range from classification, i.e., detecting whether an object or feature is present or not, localizing objects, fusing multiple sensors, to high-level scene understanding. Examples include recognizing if there are any obstacles in front of the robot, detecting road boundaries, localizing sounds or objects to be picked up, recognizing the pose of humans, self-localization, estimating depth from 2D images, or combining information from GPS, cameras, and LiDAR. Also see an example in Fig. 2. Many approaches carry over from the communities that focus on exclusively on the perception part, like computer vision. Some of the specific challenges and advantages are real-time requirements, observation noise, dealing with false positives/negatives, representing uncertainty in

Robot Learning, Fig. 2

An example for sensing combined with a model: the position of pedestrians and their heads is detected and their paths predicted based on a learned model. (Source (Kooij et al. 2019) with permission of Julian Kooij)

perception, the possibility to include information from previous time-steps, and the possibility to do *active perception*, i.e., actively influence the environment by performing actions that improve perception (Bohg et al. 2017).

Acting

Controllers can learn on very different levels. Approaches range from low-level control of motors (currents or torques) to high-level decision-making and planning. Typically, the respective lower-level controllers are assumed to be fixed, and the higher-level learning approach has to learn to cope with their imperfections. For example, we could learn a task on the trajectory level, where the trajectory provides a position and velocity reference, which is translated to low-level motor commands via traditionally designed controllers. Some approaches also learn hierarchical controllers. Elementary tasks that take place in the order of a few seconds, like grasping or individual moves in a sport, are often called motor primitives. The goal of learning can then be to learn only one such primitive, to learn how to sequence several of these to achieve more complex tasks, or to do both at the same time.

One of the popular approaches for learning controllers is called *imitation learning* or learning from demonstration, which is a form of supervised learning; see Argall et al. (2009), Billard et al. (2016) and Osa et al. (2018) for extensive surveys. Here the learning agent's task is to imitate demonstrations from a human teacher or another agent. Repeating exactly the observed behavior is not the only objective; frequently

generalization to related but previously unseen situations is more important. One of the most important questions is 'what to imitate?', i.e., determining the relevant parts of the demonstration. Imitation learning can further be subdivided in the two fields of *behavioral cloning*, where the goal is to directly imitate the control policy, and *inverse reinforcement learning* (also known as inverse optimal control), where the goal is to imitate the optimization criterion of the demonstrations. The former is a more direct form of imitation, while the latter allows for easier transfer to different embodiments and situations. Some considerations in imitation learning include the type and quality of the demonstrations and the type of controllers we want to learn (Calinon and Lee 2019). Approaches range from learning open-loop controllers, e.g., desired trajectories, to closed-loop controllers. If demonstrations are provided by kinesthetic teach-in, i.e., taking the robot by the end-effector and moving it, or via tele-operation, the input-output relations are directly contained in the demonstrations; also see an example in Fig. 3. On the other extreme, if we want to learn from instruction videos, quite a lot of additional steps are required to extract useful information and to map it to the robot morphology. A related question is how to deal with sub-optimal and contradictory demonstrations. Many inverse reinforcement learning approaches rely on the availability of models of the system dynamics to reconstruct the reward function. The general idea is that under the reconstructed reward functions, the demonstrations are optimal; all other policies are then sub-optimal. Related approaches do

Robot Learning,

Fig. 3 An example for behavioral cloning: the robot imitates the movement observed via motion capture. (Source (Calinon et al. 2010) with permission of Sylvain Calinon)

not attempt to learn the reward function from actions but rather directly from rewards or preferences the teacher assigns to various behaviors. Rather than learning behaviors or rewards from a fixed dataset, there are also interactive learning approaches that allow the teacher to provide additional demonstrations, feedback, or corrections while observing the learning process or the robot.

Another popular approach is *reinforcement learning*. Popular methods include optimal control, value function methods, actor-critic methods, gradient-based and gradient-free policy search, evolutionary strategies, and their respective deep versions. For extensive surveys, see Kober et al. (2013), Deisenroth et al. (2013), Tai et al. (2016), Arulkumaran et al. (2017), Chatzilygeroudis et al. (2019) and Sigaud and Stulp (2019). In the context of robotics, reinforcement learning has to cope with a number of specific challenges: typically its states and actions are continuous and high-dimensional. Real-world samples are expensive in terms of money and time; in most cases we want the robot to learn in a few trials, making data-hungry approaches like deep reinforcement learning difficult to apply directly. Especially, we do not want a robot to damage itself, its environment, or humans. One way to overcome this challenge is to learn the policy in simulation, i.e., based on models. However, reinforcement learning

Robot Learning, Fig. 4 An example for policy search: learning to catch the ball in the cup can be sped up by including intermittent human corrections (Source (Celemin et al. 2019) own work)

approaches tend to exploit model inaccuracies, requiring particular attention to render the transfer to real robots feasible. One approach is iteratively learning policies and improving the models. Another crucial component in reinforcement learning is the reward function, which needs to be specified by the engineer. Even if the robot perfectly learns to optimize a reward function, there might be unforeseen side effects, e.g., if you only tell the robot to remove all weeds in the garden, the flowers might be gone as well. Another important consideration

Robot Learning, Fig. 5 An example of an end-to-end architecture: the inputs are raw camera images and joint encoders, the outputs motor torques. (Source (Levine et al. 2016) with permission of Sergey Levine)

is how much the reward function should guide the learning process: on the one extreme, we have very sparse and uninformative rewards that only provide a reward once the robot has successfully completed the whole task, which typically requires very large numbers of trials. On the other extreme, we have reward functions that indicate the search direction, which allows the robot to learn faster but will not allow the robot to come up with truly novel strategies. To sum up, the specification of the reward function is often more an art than science. *Policy search* approaches and evolutionary methods have some advantages over value function-based methods in this setting as they allow more straightforward inclusion of prior knowledge, allow limiting the learning to safe updates, and often learn faster; also see an example in Fig. 4. However, this comes at the price of only optimizing locally.

End-to-End

With the recent rapid progress in deep learning, learning the whole control system simultaneously has become feasible. Rather than learning sensing and acting separately, we can now learn the mapping directly from raw sensor inputs to control actions, which might be very low level or more high level. The latter can then be seen as end-to-end learning for planning. End-to-end approaches make the learning problem significantly harder and typically require huge amounts of data. We will discuss methods to overcome this challenge in the next section. End-to-end learning has been applied to many different imitation learning and reinforcement learning problems, ranging from imitating behaviors from human demonstration videos, reinforcement learning of manipulation skills, to controlling an autonomous car; also see the example in Fig. 5

Summary and Future Directions

Robot learning spans the whole spectrum of supervised learning, unsupervised learning, and reinforcement learning and has been applied to virtually all systems and control problems in particular for sensing, acting, and models. Similar to most fields in machine learning, deep learning is currently one of the main topics and has enabled learning approaches that can deal with raw, high-dimensional sensor data. Many of the general machine learning and artificial intelligence techniques are not directly applicable to robotics due to a number of specific challenges. These, as well as steps toward overcoming them, will be outlined next.

Challenges in Robot Learning

While robots generate huge amounts of raw data, one of the biggest challenges is the high cost of *labeled* data. Tremendous effort is put into manually labeling data for supervised learning. This is similar for reinforcement learning: real robot trials are expensive, and only very few skills have been learned end-end on real robots without including task-specific prior knowledge.

Prior knowledge can be included in many different forms. The most common form is pre-structuring the learning problem and hence limiting the search space. This approach includes picking appropriate inputs and outputs to reflect what the actual interesting learning problem is, e.g., the level of the control actions or how much the inputs are pre-processed. A related approach is pre-structuring the representations, e.g., picking a suitable compact representation of the controller like a trajectory or an LQR,

defining the structure of the neural network, or even specifying a curriculum for the learning, i.e., learning a sequence of increasingly harder problems. Another form of prior knowledge is instrumented training where additional information is available during the training but no longer required once the behavior has been learned. As already mentioned above, a pre-training step can be included, e.g., a neural network might be trained first on a generic dataset, or reinforcement learning can be initialized with an imitation learning step.

Finally, models and simulators serve as a major source of prior knowledge. These can be employed to provide rough directions to steer the learning process or to completely replace data from the real system. The latter poses the problem of transferring the behaviors learned in simulation to the real system. In most cases there will be some differences between the simulation and the real world. When directly transferring the behaviors, they typically lose performance or fail completely. There are a few methods to deal with this transfer problem: we can abstract the differences away, i.e., working on a level that is sufficiently abstract that lower-level components take care of these differences. We can also make the models more similar to the real world, e.g., by incrementally learning better models or inversely learning components that make the real world more similar to the simulation. There is also the option to learn behaviors that are sufficiently robust to handle the differences, which might however result in a loss in performance. For example, the behaviors can be learned in a simulation that randomizes the visual appearance, randomizes physics parameters, adds noise, or a combination thereof that are larger than the differences between the simulation and the real system.

A final challenge is safe learning, i.e., avoiding damages to the robot and its environment. Here approaches range from traditional, low-level safety components, over enforcing gradual changes in the behavior, to approaches that explicitly consider safety in the updates. See Garcia and Fernández (2015) for a comprehensive survey in the field of reinforcement learning.

Future Directions

Many of the challenges above have been successfully addressed in various scenarios, but none of them have been solved in general. One of the major open questions still is sample efficient learning and how to deal with poor or incomplete data. Another open challenge is safe learning: How can we introduce guarantees, certification, and verification and make the learning process and the final result interpretable, especially if the system needs to generalize to previously unseen environments and situations? How do we prevent robots from learning undesirable actions, either accidentally or by malicious attacks? More generally the question of what should be learned is still open: Where and how do we best integrate traditional methods, e.g., from systems and control? How do we best integrate human expertise, experience, and intuition? Finally we have scalability questions: How do we go from learning confined tasks to learning for global systems that are interacting with an ever-changing environment and tasks? How can we make robot learning tools sufficiently robust and general to be able to create toolboxes for roboticists of other subfields and ultimately for end users in home environments and at their workplace?

Robot Motion Control

Mark W. Spong

Department of Systems Engineering, Erik Jonsson School of Engineering and Computer Science, University of Texas at Dallas, Richardson, TX, USA

Abstract

The motion control problem for robot manipulators is to determine a time sequence of control inputs to achieve a desired motion. The control inputs are usually motor voltages or currents but can be translated into

velocities or torques for the purpose of control design. The desired motion is typically given by a reference trajectory, consisting of positions, velocities, and accelerations that are generated from motion planning and trajectory generation algorithms designed to calculate collision-free paths, taking into account various kinematic and dynamic constraints on the robot. In this chapter we give an overview of some basic and advanced control methods for motion control of robot manipulators.

Keywords

Inverse dynamics · Feedback linearization · Trajectory planning · Passivity-based control · PID control · Robust control · Adaptive control · Feedforward control

Introduction

We consider the motion control problem for an n -degree-of-freedom robot manipulator, such as shown schematically in Fig. 1. The variables $\theta_1, \dots, \theta_n$ are the *joint variables*, which define the *configuration* of the robot at each instant of time. The manipulator *kinematics* defines the position and orientation, also called the *pose*, of the robot end-effector as a function of the joint variables.

A robot manipulator is fundamentally a positioning device *designed to move material, parts, tools, or specialized devices through variable programmed motions for the performance of a variety of tasks* (Robot Institute of America, 1980). Thus, manipulator tasks, such as materials transfer, welding, painting, and even tasks involving the control of interaction forces, such as assembly or grinding, are performed through the coordination of the motion of the joints of the robot. A typical robot control architecture is shown in Fig. 2, which is designed to translate *sensing* into *action* through motion planning, trajectory generation, and feedback control. In this entry we concentrate on the function of the controller.

Robot Motion Control, Fig. 1 Six-link robot manipulator. The values of the joint variables determine the position and orientation of the end-effector

Motion Planning

The desired joint motions are specified as reference trajectories (positions, velocities, and accelerations) generated from motion planning algorithms that must determine collision-free paths for the manipulator taking into account various kinematic and dynamic constraints on the robot (Lavelle 2006). A detailed discussion of motion planning is outside the scope of this entry. The motion planning problem begins by decomposing a given task into a discrete set of end-effector motions. A continuous path for the end-effector in the *task space* is then computed, taking into account issues of joint limits and collisions with objects in the workspace, including self-collisions. Finding optimal paths in configuration space is computationally complex, and methods have been developed to determine feasible, suboptimal paths using various methods such as artificial potential functions, grid search, and roadmaps (Lavelle 2006).

Once a feasible path in task space is determined, a *trajectory*, which is a time-parameterized function in task space or configuration space, is computed. To compute configuration space or joint space trajectories from task space trajectories, the *inverse kinematics* of the manipulator is used.

Robot Motion Control, Fig. 2 Control architecture for robot control. The controller is designed so that the joint variables track the reference trajectory based on sensory

feedback. Not shown are noise and disturbance inputs, which limit the achievable performance of the controller

Trajectory Generation

To simplify computation, joint-level trajectories are typically generated by calculating the inverse kinematics only at discrete points along the task space trajectory and then interpolating between these points. Two of the most common interpolation schemes utilize either *polynomials* in time or *trapezoidal velocity* profiles. Figures 3 and 4 show examples of a cubic polynomial trajectory and a trapezoidal velocity trajectory, respectively.

The control design objective is to choose the control in such a way that the plant output, θ , tracks or follows a desired output, given by the reference signal, θ^r . The control signal, however, is not the only input acting on the system. *Disturbances*, which are really inputs that we do not control, also influence the behavior of the output. Therefore, the controller must be designed, in addition, so that the effects of the disturbance on the plant output are reduced. If this is accomplished, the plant is said to *reject* the disturbances. The twin objectives of *tracking* and *disturbance rejection* are central to any control methodology.

Independent Joint Control

The simplest approach to control design for a multi-degree-of-freedom manipulator is to treat

each joint of the robot as a single-input/single-output (SISO) system and design independent controllers for each joint. The dynamic coupling among the joints is treated as a disturbance. *Proportional, integral, derivative (PID)* control is the most common method employed in this case. This approach works well for geared manipulators moving at relatively low speeds, since a large gear reduction and low speed tend to reduce the coupling effects among the various links.

Let the dynamics of a single degree-of-freedom (joint) of a robot be represented as

$$J\ddot{\theta} + B\dot{\theta} = u + d$$

where θ is the joint angle, u and d are the control input and disturbance input, respectively, with units of *torque*, and J and B represent the joint inertia and damping, respectively. A PID compensator for the above system is of the form

$$u(t) = K_P e(t) + K_I \int_0^t e(\sigma) d\sigma + K_D \frac{de}{dt} \quad (1)$$

where $e(t) = \theta(t) - \theta^r(t)$ is the *tracking error*. The controller parameters are the *proportional gain* K_P , *integral gain* K_I , and *derivative gain* K_D . A block diagram of the system is shown below in Fig. 5. The *plant* $P(s)$ and *compensator* $C(s)$ transfer functions are

$$P(s) = \frac{1}{Js^2 + Bs} \quad (2)$$

Robot Motion Control, Fig. 3 A cubic polynomial reference trajectory. Position (left); velocity (center); acceleration (right) versus time

Robot Motion Control, Fig. 4 Trapezoidal velocity profile. Position (left); velocity (center); acceleration (right) versus time

Robot Motion Control, Fig. 5 The system with a PID compensator. K_P , K_I , and K_D are the proportional, integral, and derivative gains. θ^r is the joint angle reference signal to be tracked and D is the disturbance input

and

$$C(s) = K_P + K_D s + K_I/s$$

$$= \frac{K_D s^2 + K_P s + K_I}{s} \quad (3)$$

A special case of the PID compensator is a PD compensator in which the integral gain K_I is set to zero. Referring to Equation (3), the PID Compensator adds a pole (at $s = 0$) and two zeros (roots of $K_D s^2 + K_P s + K_I$) to the forward transfer function (The PD compensator adds a single zero and no pole). The design problem, known as

tuning, is then to choose the PID gains K_P , K_D , and K_I to achieve the desired performance.

Two-Degree-of-Freedom Controller

In Fig. 5, the compensator acts on the error signal. If the reference θ^r is a step reference, then the derivative term will introduce an impulse at $t = 0$. To avoid this we may use the alternative architecture shown in Fig. 6, which is called a *two-degree-of-freedom* controller. In this architecture, the input to the derivative term $K_D s$ is the output signal θ , rather than the error signal

Robot Motion Control, Fig. 6 The system with a two-degree-of-freedom PID compensator

$\theta - \theta^r$, which avoids differentiating the step input θ^r at time $t = 0$, where the step function is discontinuous.

The Closed-Loop Systems

Whether we use the controller configuration in Fig. 5 or Fig. 6, we must analyze the appropriate transfer functions to assess the performance of the closed-loop systems. The transfer functions of relevance are, in each case, $G_1(s) = \frac{\Theta(s)}{\Theta^r(s)}$, the transfer function from the reference to the output, and $G_2(s) = \frac{\Theta(s)}{D(s)}$, the transfer function from the disturbance to the output. By the *Principle of Superposition* then, the overall system response, in each case, is given by

$$\Theta(s) = G_1(s)\Theta^r(s) + G_2(s)D(s)$$

Table 1 show the transfer functions $G_1(s)$ and $G_2(s)$ for the one- and two-degree-of-freedom architectures for both PID and PD compensators.

Set-Point Tracking

The *set-point tracking problem* refers to the case that the reference input θ^r is constant and arises in point-to-point motion. Since the reference input is a step signal, we will use the two-degree-of-freedom compensator in Fig. 6.

We first consider a PD compensator by setting the integral gain K_I equal to zero. In this case, we see from Table 1 that the closed-loop system is given by

$$\Theta(s) = \frac{K_P}{\Omega(s)}\Theta^r(s) + \frac{1}{\Omega(s)}D(s) \quad (4)$$

where $\Omega(s)$ is the closed-loop characteristic polynomial

$$\Omega(s) = Js^2 + (B + K_D)s + K_P \quad (5)$$

The closed-loop system will be stable for all positive values of K_P and K_D and bounded disturbances, and the tracking error $E(s)$ is given by

$$\begin{aligned} E(s) &= \Theta^r(s) - \Theta(s) \\ &= \frac{Js^2 + Bs}{\Omega(s)}\Theta^r(s) - \frac{1}{\Omega(s)}D(s) \end{aligned} \quad (6)$$

For a step reference input

$$\Theta^r(s) = \frac{\Theta^r}{s} \quad (7)$$

and a constant disturbance

$$D(s) = \frac{D}{s} \quad (8)$$

it follows directly from the final value theorem that the steady state error e_{ss} satisfies

$$e_{ss} = \lim_{s \rightarrow 0} sE(s) = \frac{-D}{K_P} \quad (9)$$

We see that the steady state error can be made arbitrarily small by making the position gain K_P large.

Robot Motion Control, Table 1 Closed-loop transfer functions using both the one- and two-degree-of-freedom architectures. a) and d) represent $G_1(s)$ in the one-degree-

of-freedom architecture. b) and e) represent $G_1(s)$ in the two-degree-of-freedom architecture. c) and f) represent $G_2(s)$

With PID Compensator	With PD Compensator
a) $\frac{K_D s^2 + K_P s + K_I}{J s^3 + (B + K_D) s^2 + K_P s + K_I}$	d) $\frac{K_D s + K_P}{J s^2 + (B + K_D) s + K_P}$
b) $\frac{K_P s + K_I}{J s^3 + (B + K_D) s^2 + K_P s + K_I}$	e) $\frac{K_P}{J s^2 + (B + K_D) s + K_P}$
c) $\frac{s}{J s^3 + (B + K_D) s^2 + K_P s + K_I}$	f) $\frac{1}{J s^2 + (B + K_D) s + K_P}$

Using a PD compensator, the closed-loop system is second order and hence the step response is determined by the closed-loop natural frequency ω and damping ratio ζ . Given a desired value for these quantities, the gains K_D and K_P can be found from the expression

$$s^2 + \frac{(B + K_D)}{J} s + \frac{K_P}{J} = s^2 + 2\zeta\omega s + \omega^2 \quad (10)$$

as

$$K_P = \omega^2 J, \quad K_D = 2\zeta\omega J - B \quad (11)$$

It is customary in robotics applications to take the damping ratio $\zeta = 1$ so that the response is critically damped. In this context ω determines the speed of response.

With $J = B = 1$, Fig. 7a shows step responses for several values of the natural frequency ω with no disturbance (left plot) and with a constant disturbance (right plot).

PID Control

Adding an integral term K_I/s to the above results in the closed-loop transfer functions b) and c) in Table 1. The PID control achieves exact steady tracking of step inputs while rejecting step disturbances, provided of course that the closed-loop system is stable.

The closed-loop system is now the third order system

$$\Theta(s) = \frac{(K_P s + K_I)}{\Omega_2(s)} \Theta^r(s) + \frac{s}{\Omega_2(s)} D(s) \quad (12)$$

with characteristic polynomial

$$\Omega_2 = J s^3 + (B + K_D) s^2 + K_P s + K_I \quad (13)$$

Applying the Routh-Hurwitz criterion to this polynomial, it follows that the closed-loop system is stable if the gains are positive, and in addition,

$$K_I < \frac{(B + K_D) K_P}{J} \quad (14)$$

A common design rule-of-thumb for PID control is to first set $K_I = 0$ and design the proportional and derivative gains, K_P and K_D , to achieve the desired transient behavior (rise time, settling time, and so forth) and then to choose K_I within the limits imposed by (14) to remove the steady state error.

Figure 8 shows the response of the system with a constant disturbance using a PID compensator. We see that the steady state error due to the disturbance is removed.

Feedforward Control

In order to track nonconstant reference signals, such as a cubic polynomial trajectory or trapezoidal velocity trajectory, a *feedforward* term may be superimposed on the PID control signal as shown in Fig. 9. Under the condition that the plant $P(s)$ is *minimum phase*, the feedforward transfer

Robot Motion Control, Fig. 7 Second order step responses with PD control. The speed of response, as measured by rise time, is faster for larger values of the natural frequency ω . Likewise, the steady-state error due to a constant disturbance is smaller for larger values of ω

Robot Motion Control, Fig. 8 Response with integral control action showing that the steady state error to a constant disturbance has been removed

Robot Motion Control, Fig. 9 Feedforward control architecture

function $F(s)$ can be taken as $1/P(s)$, the inverse of the plant. This guarantees asymptotic tracking of any time-varying reference trajectory provided the closed-loop transfer function is stable.

Advanced Control Methods

Advanced control methods generally aim to take into account issues such as dynamic coupling and

elasticity; uncertainty in the inertia parameters; and robustness to sensor noise and other effects. A common model of the dynamics of n -link, rigid robots, without consideration of friction and elasticity, is given by the so-called *Euler-Lagrange* equations (Spong et al. 2006)

$$M(\theta)\ddot{\theta} + C(\theta, \dot{\theta})\dot{\theta} + g(\theta) = u \tag{15}$$

where θ is the n -dimensional vector of joint variables as in Fig. 1. The n -dimensional vectors,

$\dot{\theta}$ and $\ddot{\theta}$, are then the joint velocities and accelerations, respectively. The $n \times n$ matrix, $M(\theta)$, is called the inertia matrix. The vectors $C(\theta, \dot{\theta})\dot{\theta}$ and $g(\theta)$ are Coriolis and centrifugal forces and gravitational forces, respectively. Equation (15) is a system of n coupled, nonlinear, second-order equations.

Feedback Linearization Control

An intuitive method of control for the system (15) is the method of *inverse dynamics*, also called *feedback linearization*, which computes the input torque u according to

$$u = M(\theta)a + C(\theta, \dot{\theta})\dot{\theta} + g(\theta) \quad (16)$$

where a is an additional (outer-loop) control. Choosing the outer-loop control a , for example, as

$$a = \ddot{\theta}^r + K_d(\dot{\theta}^r - \dot{\theta}) + K_p(\theta^r - \theta) \quad (17)$$

results in a closed-loop system, in terms of the tracking error, $e(t) = \theta(t) - \theta^r(t)$, that satisfies the linear equation

$$\ddot{e} + K_d\dot{e} + K_p e = 0 \quad (18)$$

and therefore, the tracking error converges exponentially to zero for diagonal matrices K_p and K_d with positive diagonal elements and any given reference trajectory, $\theta^r(t)$.

Robust and Adaptive Control

There are several practical challenges to the method of feedback linearization control discussed in the previous section. For example, in order to compute Equation (16), one must have exact knowledge of the parameters defining Equation (15). In addition, effects of compliance, friction, and so on are not modeled by Equation (15), and so the stability and performance of the system predicted by Equation (18) may not be achieved in practice. This has stimulated a great deal of research into robust and adaptive control, control of elasticity, and other issues.

In distinguishing between robust control and adaptive control, we follow the commonly accepted notion that a robust controller is a fixed controller designed to satisfy performance specifications over a given range of uncertainties, whereas an adaptive controller incorporates some sort of online parameter estimation. This distinction is important. For example, in a repetitive motion task, the tracking errors produced by a fixed robust controller would tend to be repetitive as well, whereas tracking errors produced by an adaptive controller might be expected to decrease over time as the plant and/or control parameters are updated based on runtime information. At the same time, adaptive controllers that perform well in the face of parametric uncertainty may not perform well in the face of other types of uncertainty such as external disturbances or unmodeled dynamics.

Robust Feedback Linearization

If we denote by $\hat{M}(\theta)$, $\hat{C}(\theta, \dot{\theta})$, and $\hat{g}(\theta)$ expressions for the terms $M(\theta)$, $C(\theta, \dot{\theta})$, and $g(\theta)$ in the equations of motion (15) based on nominal or estimated values of the true parameters, we can define a control input

$$u = \hat{M}(\theta)(a + \delta a) + \hat{C}(\theta, \dot{\theta})\dot{\theta} + \hat{g}(\theta) \quad (19)$$

where a is as defined in Equation (17) and δa represents an additional control intended to compensate for the parameter uncertainty. This leads to the state space model in terms of the tracking error e

$$\dot{e} = Ae + B\{\delta a + \eta\}$$

where η represents the *uncertainty* resulting from inexact cancellation of nonlinearities and

$$A = \begin{bmatrix} 0 & I \\ -K_0 & -K_1 \end{bmatrix}; \quad B = \begin{bmatrix} 0 \\ I \end{bmatrix}$$

Under the assumption that the uncertainty is bounded as $\|\eta\| \leq \rho(e, t)$, the control term δa can be chosen as

$$\delta a = \begin{cases} -\rho(e, t) \frac{B^T P e}{\|B^T P e\|} & ; \text{ if } \|B^T P e\| > \epsilon \\ -\frac{\rho(e, t)}{\epsilon} B^T P e & ; \text{ if } \|B^T P e\| \leq \epsilon \end{cases}$$

The Lyapunov function

$$V = e^T P e \quad (20)$$

where P is a symmetric, positive definite matrix satisfying a Lyapunov equation

$$A^T P + P A + Q = 0 \quad (21)$$

for a given symmetric positive definite matrix Q can be used to show uniform ultimate boundedness of all trajectories, where the size of the ultimate boundedness set depends on ϵ (Spong et al. 2006). This is a practical notion of asymptotic stability in the sense that the tracking errors can be made small.

Passivity-Based Control

Passivity-based control is an alternative to feedback linearization control and relies on some fundamental structural properties of the Euler-Lagrange equations, primarily *linearity in the parameters* and *passivity*.

The *passivity property* (Ortega and Spong 1989) of robot dynamics follows from the fact that the matrix $N(q, \dot{q}) = \dot{M}(q) - 2C(q, \dot{q})$ is skew symmetric (Spong et al. 2006). This property implies that the total energy E of the robot satisfies

$$\dot{E} = \dot{\theta}^T u \quad (22)$$

and can be used to design provably correct robust and adaptive control laws.

Linearity in the Parameters

The robot equations of motion are defined in terms of certain parameters, such as link masses, moments of inertia, etc. The complexity of the

dynamic equations makes the determination of these parameters a difficult task. Fortunately, the equations of motion are linear in these inertia parameters in the following sense: There exists an $n \times \ell$ matrix function $Y(q, \dot{q}, \ddot{q})$ and an ℓ -dimensional constant vector Φ such that the Euler-Lagrange equations can be written as

$$M(\theta)\ddot{\theta} + C(\theta, \dot{\theta})\dot{\theta} + g(\theta) = Y(\theta, \dot{\theta}, \ddot{\theta})\Phi \quad (23)$$

The function $Y(\theta, \dot{\theta}, \ddot{\theta})$ is called the *regressor* and $\Phi \in R^\ell$ is the *parameter vector*. The dimension of the parameter space, that is, the number of parameters needed to write the dynamics in this way, is not unique, and finding a minimal set of parameters that can parameterize the dynamic equations is difficult in general.

Passivity-Based Control

The passivity and linearity-in-the-parameters properties of the robot dynamics can be exploited to design robust and adaptive controllers for manipulators as follows. We define the control input u as

$$u = \hat{M}(\theta)a + \hat{C}(\theta, \dot{\theta})v + \hat{g}(\theta) - Kr \quad (24)$$

where the quantities v , a , and r are given as

$$\begin{aligned} v &= \dot{\theta}^r - \Lambda \tilde{\theta} ; \quad a = \dot{v} = \ddot{\theta}^r - \Lambda \dot{\tilde{\theta}} ; \\ r &= \dot{\theta} - v = \dot{\tilde{\theta}} + \Lambda \tilde{\theta} \end{aligned}$$

and K is a diagonal matrix of positive gains. Using the linearity-in-the-parameters property, the closed-loop system can be written as

$$M(\theta)\dot{r} + C(\theta, \dot{\theta})r + Kr = Y(\theta, \dot{\theta}, a, v)(\hat{\Phi} - \Phi) \quad (25)$$

In the robust passivity-based approach, the term $\hat{\Phi}$ is chosen as $\hat{\Phi} = \Phi_0 + \delta\Phi$ where Φ_0 is a fixed nominal parameter vector and $\delta\Phi$ is an additional control term. The additional term $\delta\Phi$ can be designed according to

$$\delta\Phi = \begin{cases} -\rho \frac{Y^T r}{\|Y^T r\|} & ; \text{ if } \|Y^T r\| > \epsilon \\ -\frac{\rho}{\epsilon} Y^T r & ; \text{ if } \|Y^T r\| \leq \epsilon \end{cases}$$

where ρ is a (constant) bound on the parameter uncertainty. Uniform ultimate boundedness of the tracking errors follows using the Lyapunov function

$$V = \frac{1}{2} r^T M(\theta) r + \tilde{\theta}^T \Lambda K \tilde{\theta}$$

where, as before, the size of the ultimate boundedness set depends on the parameter ϵ .

In the adaptive version of this approach, we consider again the control law (24) and the resulting closed-loop system

$$M(\theta)\dot{r} + C(\theta, \dot{\theta})r + Kr = Y(\hat{\Phi} - \Phi)$$

In this case, the term $\hat{\Phi}$ is taken as the output of an estimator

$$\dot{\hat{\Phi}} = -\Gamma^{-1} Y^T(\theta, \dot{\theta}, a, v) r \quad (26)$$

The Lyapunov function

$$V = \frac{1}{2} r^T M(\theta) r + \tilde{\theta}^T \Lambda K \tilde{\theta} + \frac{1}{2} \tilde{\Phi}^T \Gamma \tilde{\Phi}$$

can be used to show global convergence of the tracking errors to zero and boundedness of the parameter estimates (Spong et al. 2006).

Summary and Future Directions

We have discussed the commonly applied methods of PID control, feedback linearization control, and passivity-based control for motion control of robot manipulators. There is a large and relatively mature body of literature on these methods, and in fact, the material here is now contained in standard textbooks in robotics, such as (Spong et al. 2006).

Future directions in robot motion control include the full integration of vision, force, and position feedback, cooperative control of multiple arms, and advances in machine learning and human-robot interaction. Direct control of

robots through brain-machine interfaces is also an active area of research and will enable new areas of applications such as medical assistive robots.

Recommended Reading

Many of the fundamental theoretical problems in motion control of robot manipulators were solved during an intense period of research from about the mid-1980s until the early-1990s during which time researchers first began to exploit the structural properties of manipulator dynamics such as feedback linearizability, skew symmetry and passivity, multiple time-scale behavior, and other properties. For a more advanced treatment of some of these topics, the reader is referred to Spong et al. (1992) and Canudas de Wit et al. (1996). A survey of robust control of robots is found in Abdallah et al. (1991). The passivity-based robust control result here is due to Spong (1992). The first results in passivity-based adaptive control of manipulators were in Horowitz and Tomizuka (1986) and Slotine and Li (1987). The Lyapunov stability proof of passivity-based adaptive control is due to Spong et al. (1990). A unifying treatment of adaptive manipulator control from a passivity perspective was presented in Ortega and Spong (1989).

Abstract

Robots may allow human beings to physically interact with remote objects and environments. This possibility is known as *robot teleoper-*

ation and permits to operate in conditions or environments dangerous for human operators. Although teleoperation was among the first developments in robotics back in the 1950’s, still nowadays there are important and difficult challenges for researchers and scientists, showing the intrinsic difficulties of this fascinating field of robotics.

Keywords

Bilateral control · Force reflection · Robot teleoperation · Time delay

Introduction

A robotic teleoperation system allows to reproduce the actions of a human operator and to interact physically with objects and environments placed at a distance. This possibility has always attracted the human being, and telemanipulation has been one of the first fields to be developed in robotics: the first modern applications of this type of technology are dated back to the 1940s and the early 1950s for handling radioactive material (Goertz and Thompson 1954), for underwater and space applications (Martin and Kuban 1985; Vertut and Coiffet 1986), and for human prostheses (Kobriniskii 1960). For an overview on applications, see Sheridan (1992), Hokayem and Spong (2006), Ferre et al. (2007) and the related references. Nevertheless, despite the research interest and the many existing devices, many challenging problems have still to be fully solved both from the technical and control point of view.

In these notes, an overview on robot teleoperation is presented. In particular, the following points are illustrated:

- General description of a telemanipulation system and of its key components: the “*master*,” the “*slave*,” and the “*communication channel*”
- Overview on applications and existing devices
- Some control techniques for telemanipulation systems: “traditional” force reflection, shared compliance control, Passivity-based control, predictive control, four-channel architecture

General Description of a Telemanipulation System

A telemanipulator is a complex mechatronic system in which the main elements are a *master* (or local) and a *slave* (or remote) device, interconnected by a *communication channel*. The overall system is interfaced on one side (the master) with a human operator and on the other (the slave) with the environment: see Fig. 1.

Both the master and slave devices have a local controller, with a hardware/software complexity that can be quite different depending on the system and task to be executed. Key features of this type of devices, usually not present in a typical robotic manipulation system, are:

1. A human operator is involved in the loop for the (high-level) control of the task execution.
2. It is necessary to provide to the operator, possibly in real time, data related to the task. This implies the presence of a suitable user interface and the selection of proper signals transmitted to the operator. These signals, e.g., related to forces applied to the environment, relevant positions of the slave, graphical video

data, and tactile or acoustic information, have strong implications on the control properties and performances of the system.

3. A communication channel is present between the master and the slave. This channel may represent a source of problems when time-delays are present since, as well known from the control theory, delays in a feedback loop may generate instability. Problems of this type, firstly observed in a force feedback scheme in 1965 (Ferrel 1966), arise, for example, in underwater or space operations. Note that even time-delays of the order of the tenth of a second may create instability problems.

In the block diagram of Fig. 1, some implicit choices have been made. The operator specifies a desired velocity ($\dot{x}_m$) to be applied to the environment through the master, the communication channel, and the slave and receives back a force signal (f_{md}). In the figure, the flow of the signals could be reversed as well, letting the operator specify a force to the environment and receiving back a velocity information. This is equivalent to reversing the roles of the master and slave

Robot Teleoperation, Fig. 1 A telemanipulation system and its block scheme representation. Subscripts m and s refer to variables at the master and slave site, respectively

devices. When this operation is possible, the teleoperation system is defined *bilaterally controlled* (Bejczy and Handlykken 1981).

One of the goals of the control system is to have, in steady state, the slave velocity equal to the master velocity, i.e., $\dot{x}_s = \dot{x}_m$, and similarly for the forces, $f_{md} = f_s$. When this is accomplished, the teleoperator is defined *transparent* (Lawrence 1993).

In this general framework, the main features of the components of a telemanipulator are the following.

The Master

The master, or local system, is the interface through which the operator specifies commands to the whole device. Typical features of the master are:

- Capability of assigning tasks to the slave and providing the operator with relevant information about the task development. In fact, an important feature of the master is its capability of providing the operator with the *telepresence*, i.e., the sensation of being in some manner involved with task execution. In this respect, several solutions have been adopted, varying from joysticks and/or consoles (Hirzinger et al. 1992) to exoskeletons (Smith et al. 1992; Bergamasco et al. 2007) and so on. In these devices, different types of signals may be reflected to the operator, from simple graphical data to full kinetostatic information.
- Capability of acquiring and processing data from both the operator and the slave. Typical elaborations are filtering, prediction, delay compensation, modeling of remote and local dynamics, and so on.

The Slave

The slave, or remote system, is the part of the teleoperator which directly interacts with the environment for task execution. Requirements similar to the master may be specified for the slave system:

- A robotic system for the interaction with the environment and the execution of the task planned by the operator. This part, usually provided with autonomous features, has to be in some way customized to operate in particular environments, e.g., submarine, outer space, and nuclear areas. Note that the kinematics and the dynamics of the remote manipulator may be different from those of the local one (when present), originating several problems when telepresence is needed for task execution (Colgate 1993).
- Signal acquisition and processing. Sensory capability is a main requirement for the slave device, which is often equipped with video cameras, force/tactile sensors, proximity sensors, and so on.
- Capability of data processing. Also the remote site must be able to elaborate the information needed for task execution. In fact, besides other considerations, the destabilizing effects caused by communication delays and/or restricted bandwidths of transmission must be compensated locally, providing the slave system with a certain degree of autonomy.

The Communication Line

The communication line represents the link between the master and slave sites. Different platforms may be used for this purpose, from radio connections by means of satellites to cables for underwater operations. The main drawback that can be introduced by this element is a delay, due both to a physical delay in the transmission line (e.g., in a long satellite communication) and to limited bandwidth of the hardware. This delay, that sometimes is not even constant, can cause noticeable instability problems if proper compensating actions are not taken.

An Overview on Applications

Use of telemanipulators, in the broader sense of the terminology, may be found in a number of different applications developed since the early

1950s. First examples of these devices have been designed and realized for operations in radioactive environments and for human limb prostheses. At the moment, this type of technology is applied in a number of different fields: space, underwater, medicine, hazardous environments, security, simulators, and so on.

Space Applications

Robotics is used in space for exploration, scientific experiments, and commercial activities. Main reasons of space telerobotics are the high costs and the hostile environment for human beings. For many years, the main example of teleoperation in space was applications in space shuttle activities where the operators had a direct control of the task executed by the manipulator. Nowadays, an important application of robot technology is for planetary missions, where autonomous telerobots are required and the operator has only a supervisory control of the task. Main directions of current research activity for space robotics are the development of arms for both intra-vehicular and extravehicular activities, free-flying platforms, and planetary rovers.

Among the most known examples of robot arms for space one can list the Canadian Remote Manipulator System (RMS), installed on the US space shuttles. The 6 degree-of-freedom (dof) arm, built by the Canadian firm SPAR, had a flexible, 15 m long structure and was capable of executing preprogrammed and/or teleoperated tasks. Five arms have been built, working on space shuttles from 1981 to 2011. Since 2001 the Canadarm 2 is used on the ISS (International Space Station). This 7 dof, 17.6 m long arm is used for assembly and maintenance purposes.

Concerning planetary exploration, a first successful space telerobotic program has been the Mars Viking Program, which performed scientific experiments on Mars in 1976. More recently, NASA has sent to Mars the rovers Sojourner in 1997 (working for about 3 months) and Spirit and Opportunity, which arrived in 2004. Opportunity is still working (January 2014), see <http://marsrovers.jpl.nasa.gov/home/index.html>. New missions on Mars with other,

more complex, rovers are currently planned by NASA.

With the current technological possibilities, further substantial developments in this field are slowed down by the large amount of money and time required to guarantee a successful mission. However, relevant technical problems still exist due to reliability requirements, weight constraints, hostile environments and communication time-delays (ranging from 1 s in earth orbits to 4–40 min or more for planetary missions).

Underwater

After the first successful military applications of underwater telerobotics (in 1966 the US Navy's CURV – Cable-controlled Underwater Recovery Vehicle – was successfully employed to retrieve a nuclear bomb from the ocean), extensive use of ROVs (remote operated vehicles) has started in the 1980s for offshore operations for oil/gas industry. At the moment, underwater telerobotics is mainly used for business, military missions, and scientific expeditions. Telerobotic (autonomous) tasks are usually limited to small routine tasks rather than complete activities, for example, simple tool switching operations, repetitive bolt/nut screwing, and piloting to new locations. First examples of underwater teleoperation were mainly based on manned submersibles, either free swimming or connected to a surface ship, and with teleoperated arms on the outer structure. In more recent operations, human operators remotely control the submersibles by long fiber-optic cables for data communication, increasing the costs and complexity of the missions.

Probably, the most important users are in the business field, where it is more convenient to use teleoperated devices rather than human divers to perform inspections and repairs on deep sea equipment. The main users of telesubmersibles are the oil and communication (telephone) industries, where underwater pipes and cables require routine operations. The scientific community uses this technology for marine biological, geological, and archeological missions, while the military have used telerobotics in many salvage operations, such as plane or watercraft recovery.

The conditions of the water environment, e.g., the high pressures, the poor visibility, and the communication difficulties, cause the major problems in this field. In order to solve the problems due to the high pressure, a very robust mechanical structure and (typically) hydraulic actuators are employed. On the other hand, vision problems are not so easily solved, being related to several factors of the environment. External lighting is necessary, and other technologies (e.g., sonar) are sometimes used. Computer graphic simulation may help the user during task execution in partially known environments. For references, see, e.g., Ridao et al. (2007).

Medical Telerobotics

Several teleoperated devices are found in the medical field. In fact, robotic manipulators are used to perform surgery, diagnose illnesses or injuries, help impaired people, and train specialized medical personnel.

Robotic systems of different complexities have been developed since the 1950s for aid to impaired people. Among the most common systems are automated wheelchairs, controlled by voice or by joysticks for hand, mouth, eye, or head movements.

At the moment, there is a relevant interest in applying teleoperated devices in microsurgery operations, e.g., eye surgery, where small precise movements are needed. The movements of the operator are scaled down by the mechanism so that very fine operations can be performed while maintaining a suitable telepresence effect. Another important class of surgical process consists of the so-called minimally invasive procedures. In this case, the surgeon operates through small insertions using thin medical instruments and small video cameras. The increased difficulties for the surgeon are partially compensated by computers, which are used to create virtual environments where the use of telepresence plays a fundamental role.

A very attractive application is the use of telemanipulators in remote surgery operations. Tele-diagnosis may also broaden the range of a single doctor by allowing to exam a patient visually or

viewing records on a computer interface. Finally, telepresence is becoming very important for the instruction of specialized doctors and to perform rehearsals before the actual operation.

Security

Applications in this area aim to employ telerobotic devices for the protection of persons and properties. Most systems used in this area are teleoperated devices since these tasks require decision capabilities and intelligence levels not currently possible for machines, although the use of autonomous systems is more and more frequent.

In the area of security, robots may be used for patrolling buildings and for protection purposes. These devices can either be autonomous or teleoperated. Military applications adopt principally teleoperation, mainly for locating enemies or dangerous equipment without direct risk for human personnel. Unmanned aeroplanes or teleoperated devices for the detection and destruction of mines or bombs are well-known examples of this technology. Teleoperation is also used for fire extinguishing, in order to spray water or chemical agents with remotely operated vehicles.

Telerobotics in Hazardous Environments

Robots may substitute human beings for operations in hazardous environments; as a matter of fact, nuclear industry was the first important user of modern teleoperating devices. Telerobotics is applied in several nuclear or chemical plants and also for military applications (e.g., for building military equipment and arms) in a variety of tasks. Besides direct handling of radioactive or chemical material, robots are used in waste cleanup/disposal and plant inspection. Ammunition disposal also makes use of telerobotic machines.

Telerobotics in Mining and Other Industries

Besides the typical use of robots in a number of industrial applications (assembly, welding, painting, and so on), other applications of robotic

systems in nonconventional production processes have been developed, for example, in mines, constructions, agriculture, warehousing, and many other activities.

Use of telemanipulators for mining applications, despite the relevant motivations such as high costs and risks of human work, finds difficulties and limitations caused by the particular environment and the relevant level of autonomy requested to operate in mines. As a matter of fact, the mining industry has only recently started to experiment teleoperated devices; see e.g., Duff et al. (2010). These machines are being developed to perform frame wall building, structure testing, hole drilling, wall blasting, mine digging, and so on.

In construction tasks, not considering that all construction/destruction machinery controlled by a human can be regarded as examples of teleoperators (e.g., cranes and front-end loaders), applications of real telerobotic systems are not so numerous because of the unstructured environments and the nonrepetitive tasks. Current work in this area concerns the development of machines for earth movement, construction of structures, building window washing, bridge inspection and maintenance, and power line repair.

The Control Problem

For the development of a reliable teleoperation system, providing force feedback to the user, the problems caused by the interaction of the robotic device with the environment and the possible time-delays caused by the communication channel have to be properly considered and solved.

In telemanipulation without either force feedback to the operator or a local compliance control, the remote manipulator is strictly controlled according to the master position signal. As a consequence, the system results in being stiff, and errors between the master and slave positions may cause excessive and undesired contact forces.

In bilateral telemanipulation, it has been proven that a profitable manner for increasing system performances (e.g., in terms of task completion time, total contact time, and cumulative contact force) is to reflect back to the operator information about the force applied to the environment. On the other hand, it results that the force reflection gain, that gives to the operator the feeling of the interaction, destabilizes the system, especially when time-delays are present.

Robot Teleoperation, Fig. 2 Possible structures of bilateral control schemes for robotic teleoperation

Control schemes for robotic teleoperation devices can be classified according to the general structures reported in Fig. 2, showing the *direct teleoperation*, the *coordinated teleoperation*, and the *supervisory control* schemes. In the direct teleoperation scheme, possible only for negligible time delays, the operator has direct control of the slave robot and receives feedback in real time. In the coordinated teleoperation scheme, the operator still controls the remote robot, but low-level control loops in the slave system are present because time delays do not allow the operator to control directly the actuators. In the supervisory control scheme, the remote site has more autonomy and task execution is controlled locally, while the operator gives mainly high-level commands and acts as a supervisor. A local loop is present also at the master side, indicating the presence of (usually) a model (graphical, mathematical, etc.) of the slave site to improve performances in case of large time delays.

Some of the main control architectures for teleoperation devices presented in literature to deal with the problems of time-delay and force reflection are now briefly described and commented. The considered architectures are the “*traditional*” *force reflection*, the *shared compliance control*, the *passivity-based teleoperation*, the *predictive control*, and the *four-channel scheme*. However, many other control schemes have been presented in the literature; see, e.g., Arcara and Melchiorri (2002), Hirche et al. (2007), and therefore what is presented here is a brief, though significant, overview in order to focus on the major problems encountered in this field and on some of the approaches for their solutions.

Traditional Force Reflection Teleoperation

The simplest manner of transmitting the remote force to the operator is to reflect it directly, without any particular elaboration, as shown in Fig. 3. The resulting transmission equations are

$$\begin{cases} f_{md}(t) = f_s(t - T) \\ \dot{x}_{sd}(t) = \dot{x}_m(t - T) \end{cases} \quad (1)$$

Robot Teleoperation, Fig. 3 The “traditional force reflection” transmission scheme

where T is the time-delay introduced by the communication network and subscript d indicates the desired set point for the master (m) and slave (s) controllers.

This technique presents relevant instability problems due to time-delays. As a matter of fact, it is possible to verify that the communication channel does not present strictly passive properties, even for limited bandwidths of the input signals $\dot{x}_m$ and f_s . This result is valid also considering an attenuation between f_{md} and f_s , i.e., introducing a force reflection gain $G_{fr} < 1.0$ in (1) and computing therefore $f_{md}(t) = G_{fr} f_s(t - T)$. The attenuation reduces the telepresence sensation and degrades the performances, but still does not cause a passive (then stable) network. The nonpassive channel has the global effect of introducing in the overall system energy flows that, if not properly reduced by the local controllers, contribute to destabilize the telemanipulator.

The dynamics of the overall system may be described by the following two sets of equations: the first taking into account the master dynamics and the force transmitted by the communication channel and the second including the slave dynamics, the position signals of the channel, and the local position controller:

$$\begin{cases} M_m \dot{x}_m(t) = -f_{md}(t) - B_m \dot{x}_m(t) - K_h x_m(t) \\ f_{md}(t) = f_s(t - T) \\ M_s \dot{x}_s(t) = f_s(t) - B_s \dot{x}_s(t) \\ \dot{x}_{sd}(t) = S_p \dot{x}_m(t - T) \\ f_s(t) = K_p [x_{sd}(t) - x_s(t)] \end{cases}$$

In the above equations, M_i and B_i , $i = m, s$, are masses and damping factors at the master

and slave sites, K_h represents the operator (simply modeled as a stiffness) and K_p the slave position controller. The gain S_p has been added, with respect to Eq. (1), in order to scale velocity variables between the two robotic systems.

It can be shown that this control scheme does not guarantee stability in the presence of time delays, although in practical applications stability may still be achieved for small time delays due to dissipation introduced by friction and the local controllers.

Shared Compliance Control

As previously mentioned, both the interactions of the robotic device with the environment and the effects of time-delays have to be considered in the definition of control strategies for telemanipulation systems. The *position-error based force reflection* scheme deals with both these effects (Kim et al. 1992). This scheme is based on the computation of the feedback signal f_{md} as a force proportional to the error between master and slave positions:

$$f_{md}(t) = G_{fr} [x_m(t) - x_s(t - T)]$$

This signal gives to the operator a sensation related to the difference between the postures of the robotic devices caused either by interactions or delays. Note that in this manner an elastic (proportional) element is introduced between the positions of the robots. This allows to obtain a stable behavior of the overall system compre-

hensive of local controllers, at least for limited values of G_{fr} .

An additional feature for dealing with problems due to time-delays is the so-called *shared compliance control* (SCC). A local, autonomous force feedback is realized at the slave site in order to program active compliance and damping of the robotic device. This control action is important when compliance has to be realized between the (stiff) mechanical device and its environment and during the collision or contact phases. The overall control system is therefore based on sharing autonomous and human-driven control actions. A block diagram of the whole system, including the master and slave dynamics ($1/(M_ms^2 + B_ms + K_h)$ and $1/(M_ss^2 + B_ss)$ respectively), the force reflection gain (G_{fr}), the shared compliance controller (G_{cc}), and an environment model (K_e), is shown in Fig. 4.

For a given time-delay, the force reflection gain G_{fr} can be increased with respect to the traditional force reflection scheme. In any case, when the time-delay increases, the gain has to be correspondingly decreased to guarantee stability, i.e., the value of G_{fr} depends directly on the amount of time-delay. In fact, also this control scheme in general does not present passivity features, although it can be shown that it may be stable (for a limited range of time delays) with a proper choice of the control parameters.

Passivity-Based Teleoperation

A control scheme inspired by the passivity theory (Van der Schaft 2000) is now described. Basic

Robot Teleoperation, Fig. 4 Position-error based force reflection with SCC at the remote site

consideration is that the communication channel may represent, if proper actions are not taken, a non-passive element between the master and slave. With proper modifications, the transmission line presents passive properties, and therefore, the stability of the overall system may be achieved for any value of the time-delay T .

Lossless Transmission Line

Results of passivity and scattering theories can be used to show that in traditional force reflection teleoperation, Eq. (1), the instability of the overall system in presence of time-delays is caused by the non passive properties of the communication channel (Niemeyer and Slotine 1991). On the other hand, it has been shown that the definition of a communication network based on a lossless transmission line provides the system with passivity features for any time-delay (Anderson and Spong 1989), facilitating therefore the stability of the overall system.

For the definition of a lossless transmission line, it is convenient to refer, instead of the velocity and force variables $\dot{x}$, f at each port (see Fig. 3), to the equivalent *wave* variables u and v that are related to the passivity formalism and whose definition derives from the theory of electric circuits. By using these variables, it is possible to describe the power balance in a circuit as the difference of two positive terms which consider the input and the output power. In fact, by introducing the input wave $u = [u_m^T, u_s^T]^T$ and the output wave $v = [v_m^T, v_s^T]^T$, the power balance in the teleoperator can be expressed as

$$P = \frac{1}{2} (u^T u - v^T v) = f^T \dot{x} = [f_m^T, f_s^T] \begin{bmatrix} \dot{x}_m \\ -\dot{x}_s \end{bmatrix}$$

By considering a proper scaling factor b , defined as the *characteristic impedance* of the transmission line, the previous equation defines the following transformations between power and wave variables:

$$\begin{aligned} u_m &= \frac{1}{\sqrt{2b}}(f_m + b \dot{x}_m) & u_s &= \frac{1}{\sqrt{2b}}(f_s - b \dot{x}_s) \\ v_m &= \frac{1}{\sqrt{2b}}(f_m - b \dot{x}_m) & v_s &= \frac{1}{\sqrt{2b}}(f_s + b \dot{x}_s) \end{aligned}$$

The resulting network is described by

$$\begin{cases} f_{md}(t) = f_s(t - T) + b[\dot{x}_m(t) - \dot{x}_{sd}(t - T)] \\ \dot{x}_{sd}(t) = \dot{x}_m(t - T) + \frac{1}{b}[f_{md}(t - T) - f_s(t)] \end{cases}$$

In terms of wave variables, the passivity-based communication network is described as (see Fig. 5)

$$\begin{cases} f_{md}(t) = b \dot{x}_m(t) + \sqrt{2b} v_m(t) \\ \dot{x}_{sd}(t) = -\frac{1}{b}[f_s(t) - \sqrt{2b} v_s(t)] \end{cases}$$

In analogy with electric networks, impedance adaptation should be added to both extremities of the transmission line, as described e.g., in Niemeyer and Slotine (1991).

Predictive Control

In a well-known example of space telerobotics, the ROTEX project (Hirzinger et al. 1992), the problems introduced by force feedback and time-delays have been solved in a different manner. In fact, in this case the force information is not transmitted to the operator, and an extensive use of graphic simulation and *telesensor programming* is made to help control of the task execution.

In particular, the *predictive display* technique (Sheridan 1992) has been employed for generating and extrapolating beforehand visual indications, such as cursors or wire frame models of the manipulator and its environment. These information are generated by the control system and assist the operator in driving the task execution more efficiently. In this case, a proper prediction algorithm has to be set on the basis of current initial conditions of the manipulator and, possibly, of current control variables.

In telerobotics, predictive displays have to be purposely designed in order to consider the prediction of motions of the manipulator. Usually, the task is graphically simulated in real time, without time-delay, exploiting a model of the remote environment and of the slave device. The operator can observe the task executed by the remote system on the screen, where a simulated copy (with $T = 0$ s) of the robotic device can

Robot Teleoperation, Fig. 5 Transmission line based on passivity

Robot Teleoperation, Fig. 6 Block scheme of the four-channel architecture. (a) The human operator. (b) Master controller. (c) Communication line. (d) Slave controller. (e) Environment

be superimposed on the real operating device in the scene of the remote site. In this manner, the operator may program appropriate actions for the interaction with the environment.

This type of task planning helps when a noticeable time-delay occurs. In fact, when operators deal with relevant time-delays (e.g., larger than 1 s), usually they operate with a “move and wait” strategy, conservatively specifying only small displacements to the remote robot. By using predictive display, the time required to execute complex tasks is greatly reduced. On the other hand, the operator has only visual information about the remote environment and the task execution.

Four-Channel Scheme

A generalization of the scheme of Fig. 1, the so-called four-channel architecture (Hirche et al. 2007; Lawrence 1993), is shown in Fig. 6. In this scheme, both the velocity and force signal of the master and slave are transmitted, and with a proper choice of the four blocks C_1, C_2, C_3 , and C_4 many design goals can be achieved, in particular concerning the stability and the transparency of the overall system. In particular, if $C_3 = C_4 = 0$, the standard velocity-force transmission scheme is obtained, while ideal transparency is achieved if $C_1 = Z_{cs}, C_2 = C_3 = I, C_4 = -Z_{cm}$. In the figure, the blocks Z_m and Z_s represent the master and the slave dynamics

(impedances), respectively, while C_m and C_s are the local master and slave controllers, f_h^* is an external force applied by the user, and f_e^* an exogenous force from the environment.

Summary and Future Directions

In these notes, an overview on telemanipulation has been presented with the aim of giving a general presentation of the impact of this area of robotics on both industry and research, of outlining typical problems encountered in dealing with remote manipulation systems, and of illustrating some approaches for their solution.

In this respect, it has to be pointed out that, besides the control schemes considered in these notes (purposely developed for telerobotic systems), many other schemes have been presented in the literature (see, e.g., Hokayem and Spong 2006, Ferre et al. 2007, and Arcara and Melchiorri 2002). More in general, however, a relevant literature exists, and important results have been presented from a methodological point of view to face control problems of time-delay systems: see for example, Gu et al. (2003).

There are, however, other important aspects of telemanipulation which, for space constraints, can only be mentioned here, such as the “impedance shaping” (typical in applications in which there is a relevant dynamic/mechanical difference between the master and slave mechanisms) or criteria for defining (and measuring) performance of teleoperator systems, such as the “time to completion,” criteria based on energy consumption, dexterity, and so on. Other interesting, and important, extensions are the possibility of controlling remote teams of robots cooperating for the execution of a common task (e.g., for aerial inspections, transport of heavy loads, etc.).

Future developments of robotic teleoperation systems will deal with the technological improvements of the user interface, giving to the operator more “realistic” feedback of the remote environment, the application of this type of technology to more complex situations, and the use of multi-robot systems controlled either by one or more

cooperating users. Control will play in any case a fundamental role in these scenarios.

Robot Visual Control

François Chaumette

Inria, Univ Rennes, CNRS, IRISA, Rennes, France

Abstract

This entry presents the basic concepts of vision-based control, that is, the use of visual data to control the motions of a robotics system. It details the modeling steps allowing to achieve a visual task, the list of possible visual features that can be used as input of the control scheme, the design of basic kinematics control schemes, and hints toward more advanced approaches. Applications are also described.

Keywords

Robot control · Robot vision · Visual servoing · Jacobian

Introduction

Basically, visual control, also named visual servoing, consists in using the data provided by one or several cameras as input of real-time closed-loop control schemes for controlling the motions of a dynamic system so that it achieves a task specified by visual constraints (Hutchinson et al. 1996; Chaumette et al. 2016). Such systems are usually robot arms or mobile robots, but can also be virtual robots, or even a virtual camera. A large variety of positioning tasks, or target tracking tasks, can be considered by controlling from one to all the degrees of freedom (DoF) of the system (Marchand et al.

2005). Whatever the sensor configuration, which can vary from one on-board camera located on the robot end-effector to several free-standing cameras, a set of visual features has to be selected at best from the image measurements available, allowing to control the desired DoF. A control law has then to be designed so that these visual features reach a desired value, defining a correct achievement of the task. A desired planned trajectory can also be tracked. The control principle is to regulate the error between the current and desired values of the visual features to zero or, in other terms, to minimize an objective function from which Lyapunov-based stability analysis can be performed. With a vision sensor providing 2D measurements, potential visual features are numerous, since 2D data (coordinates of particular points in the image, parameters related to geometrical shapes, intensity levels of set of pixels, etc.) as well as 3D data provided by a localization algorithm exploiting the extracted 2D measurements can be considered. It is also possible to combine 2D and 3D visual features to take the advantages of each approach while avoiding their respective drawbacks.

Typically, an iteration of the control scheme consists of the following successive steps:

- acquire an image;
- extract some useful image measurements;
- compute the current value of the visual features used as inputs of the control scheme;
- compute the error between the current and the desired values of the visual features;
- update the control outputs, which are usually the robot velocity, to regulate that error to zero, i.e., to minimize its norm.

For instance, for the first example depicted on Fig. 1, the image processing part consists in extracting and tracking the center of gravity of the moving people, the visual features are composed of the two Cartesian coordinates of this center of gravity, and the control scheme computes the camera pan and tilt velocities so that the center of gravity is as near as possible of

the image center despite the unknown motion of the people. In the second example where a camera mounted on a six DoF robot arm is considered, the image measurements are a set of segments that are tracked in the image sequence. From these measurements and the knowledge of the 3D object model, the pose from the camera to the object is estimated and used as visual features. The control scheme now computes the six components of the robot velocity so that this pose reaches a particular desired value corresponding to the object position depicted in blue on the images.

Basic Theory

Most if not all visual servoing tasks can be expressed as the regulation to zero of an error $e(t)$ defined by

$$e(t) = s(m(r(t)), a) - s^*(t). \quad (1)$$

The parameters in (1) are defined as follows (Chaumette et al. 2016): the vector $m(r(t))$ is a set of image measurements (e.g., the image coordinates of points, or the area, the center of gravity, and other geometric characteristics of an object). These image measurements depend on the pose $r(t)$ between the camera and the environment, this pose varying with time t . They are used to compute a vector $s(m(r(t)), a)$ of visual features, in which a is a set of parameters that represent potential additional knowledge about the system (e.g., coarse camera intrinsic parameters or 3D model of objects). The vector $s^*(t)$ contains the desired value of the features, which can be either constant in the case of a fixed goal or varying if the task consists in following a specified trajectory. Visual servoing schemes mainly differ in the way that the visual features are designed. As represented in Fig. 2, the two most classical approaches are named image-based visual servoing (IBVS), in which s consists of a set of 2D parameters that are directly expressed in the image (Weiss et al. 1987; Espiau et al. 1992), and pose-based visual servoing (PBVS), in which s consists of a set of 3D parameters related

Robot Visual Control, Fig. 1 Few images acquired during two visual servoing tasks: on the top, pedestrian tracking using a pan-tilt camera; on the bottom, controlling the

6 degrees of freedom of an eye-in-hand system so that an object appears at a particular position in the image (shown in blue)

Robot Visual Control, Fig. 2 If the goal is to move the camera from frame R_c to the desired frame R_{c^*} , two main approaches are possible: IBVS on the left, where the

features s and s^* are expressed in the image, and PBVS on the right, where the features s and s^* are related to the pose between the camera and the observed object

to the pose between the camera and the target (Weiss et al. 1987; Wilson et al. 1996; Thuilot et al. 2002). In that case, the 3D parameters have to be estimated from the image measurements either through a pose estimation process using the knowledge of the 3D target model (Marchand et al. 2016) or through a triangulation process if a stereovision system is considered. Inside IBVS and PBVS approaches, many possibilities exist depending on the choice of the features. Each choice will induce a particular behavior of the system. There also exist hybrid approaches, named 2 1/2D visual servoing, which combine 2D and 3D parameters in s in order to benefit from the advantages of IBVS and PBVS while

avoiding their respective drawbacks (Malis and Chaumette 2000).

The Features Jacobian

The design of the control scheme is based on the link between the time variation $\dot{s}$ of the features and the robot control inputs, which are usually the velocity $\dot{q}$ of the robot joints. This relation is given by

$$\dot{s} = J_s \dot{q} + \frac{\partial s}{\partial t} \quad (2)$$

where J_s is the features Jacobian matrix, defined from the equation above similarly as the classical robot Jacobian. For an eye-in-hand system (see the left part of Fig. 3), the term $\frac{\partial s}{\partial t}$, represents

Robot Visual Control,

Fig. 3 In visual servoing, the vision sensor can be mounted either near the robot end-effector (eye-in-hand configuration) or outside and observing the end-effector (eye-to-hand configuration). For the same robot motion, the motion produced in the image will be opposite from one configuration to the other

the time variation of s due to a potential object motion, while for an eye-to-hand system (see the right part of Fig. 3) it represents the time variation of s due to a potential sensor motion.

As for the features Jacobian, in the eye-in-hand configuration, it can be decomposed as (Chaumette et al. 2016)

$$J_s = L_s {}^cV_e J(q) \quad (3)$$

where:

- $J(q)$ is the robot Jacobian such that $\dot{v}_e = J(q)\dot{q}$ where v_e is the robot end-effector velocity;
- cV_e is the spatial motion transform matrix from the vision sensor to the end-effector. It is given by Khalil and Dombre (2002)

$${}^cV_e = \begin{bmatrix} {}^cR_e & [{}^ct_e]_{\times} {}^cR_e \\ \mathbf{0} & {}^cR_e \end{bmatrix} \quad (4)$$

where cR_e and ct_e are, respectively, the rotation matrix and the translation vector between the sensor frame and the end-effector frame and where $[{}^ct_e]_{\times}$ is the skew symmetric matrix associated to ct_e . Matrix cV_e is constant when the vision sensor is rigidly attached to the end-effector, which is usually the case. Thanks to the robustness of closed-loop control schemes with respect to calibration errors, a coarse approximation of cR_e and ct_e is generally sufficient in practice

to serve as a satisfactory estimation of cV_e to be injected in the control law. If needed, an accurate estimation is possible through classical hand-eye calibration methods (Tsai and Lenz 1989).

- L_s is the interaction matrix of s defined such that $\dot{s} = L_s v$ where v is the relative velocity between the camera and the environment.

In the eye-to-hand configuration, the features Jacobian J_s is composed of (Chaumette et al. 2016)

$$J_s = -L_s {}^cV_f {}^fV_e J(q) \quad (5)$$

where:

- fV_e is the spatial motion transform matrix from the robot reference frame to the end-effector frame. It is known from the robot kinematics model.
- cV_f is the spatial motion transform matrix from the camera frame to the reference frame. It is constant as long as the camera does not move. In that case, similarly as for the eye-in-hand configuration, a coarse approximation of cR_f and ct_f is usually sufficient.

The Interaction Matrix

A lot of works have concerned the modeling of various visual features s and the determination of the analytical form of their interaction matrix L_s . To give just an example, in the case of an image point with normalized Cartesian coordinates

$\mathbf{x} = (x, y)$ and whose 3D corresponding point has depth Z in the camera frame, the interaction matrix $\mathbf{L}_x$ of $\mathbf{x}$ is given by Espiau et al. (1992)

$$\mathbf{L}_x = \begin{bmatrix} -1/Z & 0 & x/Z & xy & -(1+x^2) & y \\ 0 & -1/Z & y/Z & 1+y^2 & -xy & -x \end{bmatrix} \quad (6)$$

where the three first columns contain the elements related to the three components of the translational velocity and where the three last

columns contain the elements related to the three components of the rotational velocity.

By just changing the parameters representing the same image point, that is, by using the cylindrical coordinates defined by $\boldsymbol{\gamma} = (\rho, \theta)$ with $\rho = \sqrt{x^2 + y^2}$ and $\theta = \text{Arctan}(y/x)$, the interaction matrix of these parameters has a completely different form (Iwatsuki and Okiyama 2005):

$$\mathbf{L}_\gamma = \begin{bmatrix} -\cos \theta / Z & -\sin \theta / Z & \rho / Z & (1 + \rho^2) \sin \theta & -(1 + \rho^2) \cos \theta & 0 \\ \sin \theta / (\rho Z) & -\cos \theta / (\rho Z) & 0 & \cos \theta / \rho & \sin \theta / \rho & -1 \end{bmatrix} \quad (7)$$

This implies that using the Cartesian coordinates or the cylindrical coordinates as visual features will induce a different behavior, that is, a different trajectory of the point in the image and, consequently, a different robot trajectory. The main objective in designing a visual servoing control scheme is thus to select the best set of visual features in terms of stability, global behavior (adequate trajectories in both the image plane and 3D space), and robustness to noise and to modeling and calibration errors from the task to be achieved, the environment observed, and the available image measurements. All these aspects can be studied from the interaction matrix of the potential visual features.

Currently, the analytical form of the interaction matrix is available for most basic features resulting from the perspective projection of simple geometrical primitives such as circles, spheres, and cylinders (Espiau et al. 1992). It is also available for image moments related to planar and almost-planar objects of any shape (Chaumette 2004), as well as for features selected from the epipolar geometry (Silveira and Malis 2012) and, of course, also for coordinates of 3D points, parameters of 3D geometrical primitives, and pose parameters, assuming these features are perfectly estimated.

In the recent years, following the seminal works of Nayar et al. (1996) and Deguchi (2000), a new trend has concerned the use of direct image content as input of the control scheme (Han et al. 2010; Collewet and Marchand 2011). The main

objective of these works is to avoid the extraction, tracking, and matching of geometrical measurements, such as points of interest or edges, so that the system is extremely accurate and robust with respect to image processing errors. The basic idea is to consider the intensity of a set of pixels as visual features ($\mathbf{s} = \mathbf{I}$). From the classical assumption in computer vision stating that the intensity level of a moving point does not change (i.e., $I(\mathbf{x}, t) = I(\mathbf{x} + d\mathbf{x}, t + dt)$), it is possible to determine the interaction matrix corresponding to the intensity level of a pixel:

$$\mathbf{L}_I = -\left[\frac{\partial I}{\partial x} \quad \frac{\partial I}{\partial y}\right] \mathbf{L}_x \quad (8)$$

where $\left[\frac{\partial I}{\partial x} \quad \frac{\partial I}{\partial y}\right]$ is the spatial gradient of the intensity along the x and y directions. Proceeding so leads to control a highly nonlinear system, with the drawback of a relatively small convergence domain, and, in general, not expected robot trajectory, plus the potential issue of robustness with respect to lighting variations. That is why the idea of direct photometric visual servoing has been expended either by considering other objective functions than $\|\mathbf{I} - \mathbf{I}^*\|$, such as the mutual information between the current and desired images (Dame and Marchand 2011), or other global image representations (Duflot et al. 2019; Crombez et al. 2019), or by designing photo-geometric visual features (Bakthavatchalam et al. 2018).

All the works mentioned above have considered a classical vision sensor modeled by a perspective projection. It is possible to generalize the approach to any sort of sensors, such as omnidirectional cameras (Hadj-Abdelkader et al. 2008; Caron et al. 2013), RGB-D sensors (Teulière and Marchand 2014), the coupling between a camera and structured light (Motyl et al. 1992; Pagès et al. 2006), and even 2D echographic probes (Mebarki et al. 2010). A large variety of visual features is thus available for many vision sensors.

Finally, methods also exist to estimate offline or online a numerical value of the interaction matrix, by using neural networks, for instance (Suh 1993; Wells et al. 1996), or the Broyden update (Hosoda and Asada 1994; Jägersand et al. 1997). These methods are useful when the analytical form of the interaction matrix cannot be determined, but any a priori analysis of the properties of the system is unfortunately impossible.

Control

Once the modeling step has been performed, the design of the control scheme can be quite simple. The most basic control scheme has the following form (Chaumette et al. 2016):

$$\dot{\mathbf{q}} = -\lambda \widehat{\mathbf{J}}_s^+ \mathbf{e} + \widehat{\mathbf{J}}_s^+ \frac{\partial \mathbf{s}^*}{\partial t} - \widehat{\mathbf{J}}_s^+ \frac{\partial \widehat{\mathbf{s}}}{\partial t} \quad (9)$$

where, in the first feedback term, $\mathbf{e} = \mathbf{s} - \mathbf{s}^*$ as defined in Eq. (1), λ is a positive (possibly varying) gain tuning the time-to-convergence of the system and $\widehat{\mathbf{J}}_s^+$ is the Moore-Penrose pseudoinverse of an approximation or an estimation of the features Jacobian. The exact value of all its elements is indeed generally unknown since it depends on the intrinsic and extrinsic camera parameters, as well as on some 3D parameters such as the depth of the point in Eqs. (6) and (7). Methods for estimating these 3D parameters exist, either using the knowledge of the robot motion (De Luca et al. 2008) or, up to a scalar factor, from partial pose estimation using the properties of the epipolar geometry between the current and the desired images (Malis and Chaumette 2000).

The second term of the control scheme anticipates for the variation of $\mathbf{s}^*$ in the case of a varying desired value. The third term compensates as much as possible a possible target motion in the eye-in-hand case and a possible camera motion in the eye-to-hand case. They are both null in the case of a fixed desired value and a motionless target or camera. They serve as feedforward terms for removing the tracking error in the other cases (Corke and Good 1996).

Following the Lyapunov theory, the stability of the system can be studied (Chaumette et al. 2016). Generally, visual servoing schemes can be demonstrated to be locally asymptotically stable (i.e., the robot will converge if it starts from a local neighborhood of the desired pose) if the errors introduced in $\widehat{\mathbf{J}}_s$ are not too strong. Some particular visual servoing schemes can be demonstrated to be globally asymptotically stable (i.e., the robot will converge whatever its initial pose) under similar conditions. This is, for instance, the case for the pan-tilt camera control depicted on Fig. 1, for PBVS assuming the 3D parameters involved are perfectly estimated, and for well-designed IBVS schemes.

Finally, when the visual features do not constrain all the DoF, it is possible to combine the visual task with supplementary tasks such as joint limits avoidance or the visibility constraint (to be sure that the target considered will always remain in the camera field of view). In that case, the redundancy framework (Nakamura et al. 1987) can be applied and the new error to be regulated to zero has the following form:

$$\mathbf{e}_n = \widehat{\mathbf{J}}_s^+ \mathbf{e} + (\mathbf{I} - \widehat{\mathbf{J}}_s^+ \widehat{\mathbf{J}}_s) \mathbf{e}_2 \quad (10)$$

where $(\mathbf{I} - \widehat{\mathbf{J}}_s^+ \widehat{\mathbf{J}}_s)$ is a projection operator on the null space of the visual task $\mathbf{e}$ so that the supplementary task $\mathbf{e}_2$ will be achieved at best under the constraint that it does not perturb the visual task. A similar control scheme to (9) is now given by

$$\dot{\mathbf{q}} = -\lambda \mathbf{e}_n - \frac{\partial \widehat{\mathbf{e}}_n}{\partial t} \quad (11)$$

This scheme has, for instance, been applied for the first example depicted on Fig. 4 where the

rotational motion of the mobile robot is controlled by vision while its translational motion is controlled by the odometry to move at a constant velocity.

Any other more advanced control strategy can be applied such as optimal control (Nelson and Khosla 1995; Hashimoto et al. 1996), coupling path planning and visual servoing (Mezouar and Chaumette 2002; Chesi 2009; Kazemi et al. 2013), model predictive control

(Ginhoux et al. 2005; Allibert et al. 2010), or quadratic programming (Agravante et al. 2016) when visual tasks and visual constraints have to be simultaneously handled with other tasks and constraints. Particular care has to be considered for underactuated and nonholonomic systems for which adequate control laws have to be designed (Hamel and Mahony 2002; Mebarki et al. 2015; Mariottini et al. 2007; Lopez-Nicolas et al. 2010).

Robot Visual Control, Fig. 4 Few applications of visual servoing: navigation of a mobile robot to follow a wall using an omnidirectional vision sensor (top line), grasping

a ball with a humanoid robot (middle line), and assembly of MEMS and film of a dialogue within the constraints of a script in animation (bottom line)

Applications

Potential applications of visual servoing are numerous. It can be used as soon as a vision sensor is available and a task is assigned to a dynamic system. A non-exhaustive list of examples is (see also Fig. 4):

- the control of a pan-tilt-zoom camera, as illustrated in Fig. 1 for the pan-tilt case;
- grasping using a robot arm;
- locomotion and dexterous manipulation with a humanoid robot;
- micro- or nano-manipulation of MEMS or biological cells;
- pipe inspection by an underwater autonomous vehicle;
- autonomous navigation of a mobile robot in indoor or outdoor environment;
- aircraft landing;
- autonomous satellite rendezvous;
- biopsy using ultrasound probes or heart motion compensation in medical robotics.
- virtual cinematography in animation.

Summary and Future Directions

Visual servoing is a mature area. It is basically a nonlinear control problem for which numerous modeling works have been achieved to design visual features so that the control problem is transformed as much as possible to a linear control problem. On the one hand, improvements on this topic are still expected for instantiating this general approach to particular applications. On the other hand, designing new control strategies is another direction for improvements, especially when supplementary data coming from other sensors (force, tactile, proximity sensors) are available. Finally, the current expansion of deep learning may rejuvenate the field (Levine et al. 2016; Bateux et al. 2018; Pandya et al. 2019), especially for the dense direct methods that use the same input and end-to-end approach.

Robust Adaptive Control

Anuradha M. Annaswamy and
Joseph E. Gaudio

Active-adaptive Control Laboratory, Department
of Mechanical Engineering, Massachusetts
Institute of Technology, Cambridge, MA, USA

Abstract

Robust adaptive control pertains to the satisfactory behavior of adaptive control systems in the presence of nonparametric perturbations such as disturbances, unmodeled dynamics, and time delays. This entry covers the highlights of robust adaptive controllers, methods used, and results obtained. Both methods of achieving robustness, which include modifications in the adaptive law and persistent excitation in the reference input, are presented.

In both cases, results obtained for robustness to disturbances and unmodeled dynamics are discussed.

Introduction

The central problem in adaptive control pertains to regulation and tracking of systems in the presence of parametric uncertainties. The classical adaptive control problem solved in 1980 assumed that the underlying transfer function had unknown parameters, but no other uncertainties. No disturbances, delays, time variations in parameters, or unmodeled dynamics were assumed to be present. Under these ideal conditions, it was shown that an adaptive controller can be designed so that the closed-loop system has bounded signals and that asymptotic regulation and tracking were possible.

With asymptotic regulation and tracking achieved under such ideal conditions, the goal of robust adaptive control was to ensure globally bounded signals in the closed-loop adaptive system when the plant was subjected to a variety of nonparametric perturbations such as external disturbances, time-varying parameters, unmodeled dynamics, and time delays. With adaptation in the control parameters in the ideal case accommodating parametric uncertainties, the approaches developed in robust adaptive control focused on developing solutions in the perturbed case to accommodate nonparametric uncertainties and improve on the classical adaptive controller which either underperformed or even exhibited instability with the introduction of nonparametric perturbations.

We briefly present the adaptive control solutions for the ideal case before proceeding with robust adaptive control.

Classical Adaptive Control

Adaptive Control of Plants with State Feedback

One of the very first problems where stable adaptive control was solved was for the case when states are accessible (Narendra and Kudva 1974), with the plant given by (the argument t is suppressed for the sake of convenience, except for emphasis)

$$\dot{x}_p = A_p x_p + b \lambda u \quad (1)$$

where $A_p \in \mathbb{R}^{n \times n}$ and the scalar λ are unknown parameters with b and the sign of λ known and (A_p, b) controllable. An adaptive controller that ensures global boundedness and asymptotic regulation and tracking for such plants is of the form

$$u = \theta_x^T(t) x_p + \theta_r(t) r, \quad (2)$$

and the adaptive laws for adjusting the unknown parameters are given by

$$\dot{\theta} = -\text{sign}(\lambda) \Gamma \omega b^T P e, \quad (3)$$

where $\omega = [x_p^T, r]^T$, $\theta = [\theta_x^T, \theta_r]^T$, $e = x - x_m$, and x_m is the state of a reference model

$$\dot{x}_m = A_m x_m + b r \quad (4)$$

with A_m Hurwitz, and P being the solution of the Lyapunov equation $A_m^T P + P A_m = -Q$, $Q > 0$, and $\Gamma \in \mathbb{R}^{(n+1) \times (n+1)}$ a diagonal positive definite matrix. The reference model in (4) is to be chosen so that certain matching conditions are satisfied, which are of the form

$$A_p + b \lambda \theta_x^{*T} = A_m, \quad \lambda \theta_r^* = 1 \quad (5)$$

for some $\theta^* = [\theta_x^{*T}, \theta_r^*]^T$. In such a case, the controller in (2) and (3) guarantees stability and ensures that $x(t)$ tracks $x_m(t)$. The underlying Lyapunov function is quadratic in e and the parameter error $\tilde{\theta} = \theta - \theta^*$, given by

$$V = \frac{1}{2} (e^T P e + \lambda \tilde{\theta}^T \Gamma^{-1} \tilde{\theta}) \quad (6)$$

with a negative semi-definite time derivative $\dot{V}$ given by

$$\dot{V} \leq -e^T Q e. \quad (7)$$

Adaptive Control of Plants with Output Feedback

Consider the *single-input single-output* (SISO) system of equations

$$y(t) = W(s)u(t) \quad (8)$$

where $u \in \mathbb{R}$ is the input, $y \in \mathbb{R}$ the measurable output, and s the differential operator. The transfer function of the plant is parameterized as

$$W(s) \triangleq k_p \frac{Z(s)}{P(s)} \quad (9)$$

where k_p is a scalar and $Z(s)$ and $P(s)$ are monic polynomials with $\deg(Z(s)) < \deg(P(s))$. The following assumptions will be made throughout:

Assumption 1 $W(s)$ is minimum phase.

Assumption 2 The sign of k_p is known.

Assumption 3 The relative degree n^* and the order of $W(s)$ are known.

The goal is to design a control input u so that the output y in (8) tracks the output y_m of the reference system

$$y_m(t) = W_m(s)r(t) \triangleq k_m \frac{Z_m(s)}{P_m(s)} r(t) \quad (10)$$

where k_m is a scalar and $Z_m(s)$ and $P_m(s)$ are monic polynomials with $W_m(s)$ relative degree n^* .

The structure of the adaptive controller is now presented:

$$\dot{\omega}_1(t) = \Lambda \omega_1 + b_\lambda u(t) \quad (11)$$

$$\dot{\omega}_2(t) = \Lambda \omega_2 + b_\lambda y(t) \quad (12)$$

$$\omega(t) \triangleq [r(t), \omega_1^T(t), y(t), \omega_2^T(t)]^T \quad (13)$$

$$\theta(t) \triangleq [k(t), \theta_1^T(t), \theta_0(t), \theta_2^T(t)]^T \quad (14)$$

$$u(t) = \theta^T(t)\omega(t) \quad (15) \quad \text{function candidate given by}$$

where $\Lambda \in \mathbb{R}^{(n-1) \times (n-1)}$ is Hurwitz, $b_\lambda \in \mathbb{R}^{n-1}$, $\omega_1, \omega_2 \in \mathbb{R}^{n-1}$, and $\theta \in \mathbb{R}^{2n}$ is an adaptive gain vector with $k(t) \in \mathbb{R}$, $\theta_1(t) \in \mathbb{R}^{n-1}$, $\theta_2(t) \in \mathbb{R}^{n-1}$, and $\theta_0(t) \in \mathbb{R}$.

The update law for the adaptive parameter differs depending on whether the relative degree of $W_m(s)$ is unity or greater than one and can be described as follows:

$$\dot{\theta}(t) = -\text{sign}(k_p)\Gamma e_y \omega \quad n^* = 1 \quad (16)$$

and

$$\dot{\theta}(t) = -\text{sign}(k_p)\Gamma \frac{e_a \zeta}{1 + \zeta^T \zeta} \quad n^* \geq 2 \quad (17)$$

where $e_y = y - y_m$, e_a is an augmented error, and ζ is a modified regressor, both of which are determined by the following equations:

$$\zeta = W_m(s)I(s)\omega, \quad \omega = [r, \omega_1^T, y, \omega_2^T]^T, \quad (18)$$

$$e_2 = \theta^T \zeta - W_m(s)[\theta^T \omega] \quad (19)$$

$$e_a = e_y + k_1(t)e_2 \quad (20)$$

$$\dot{k}_1 = -\frac{e_a e_2}{1 + \zeta^T \zeta} \quad (21)$$

The results of Narendra and Annaswamy (2005) guarantee that the above adaptive controller in Eqs. (11)–(21) will guarantee that $e_y(t)$ tends to zero as $t \rightarrow \infty$ with all signals remaining bounded in both the $n^* = 1$ and $n^* \geq 2$ cases.

Need for Robust Adaptive Control

When a disturbance η is present, the plant dynamics often is of the form

$$\dot{x}_p = A_p x_p + b\lambda(u + \eta(t)) \quad (22)$$

while the reference model and the controller remain the same as in (4) and (2), respectively. This in turn necessitates new tools for the analysis and synthesis of adaptive systems. The main reason for this is the fact that the standard Lyapunov

$$V = \frac{1}{2}e^T P e + \frac{1}{2}\lambda \tilde{\theta}^T \Gamma^{-1} \tilde{\theta} \quad (23)$$

together with the parameter adjustment as in (3) yields a time derivative

$$\dot{V} \leq -\frac{1}{2}e^T Q e + k_1 \|e\| d_0 \quad k_1 > 0, \quad (24)$$

where d_0 is an upper bound on the perturbation η . The second term on the right-hand side of (24) causes $\dot{V}$ to be sign indefinite. This is because V is a function of both e and $\tilde{\theta}$, and therefore, the second term can be large compared to the first with the second argument of V , $\tilde{\theta}$, which can be arbitrary, causing $\dot{V}$ to be sign indefinite. This property causes $\dot{V}$ to be semi-definite in the ideal case. Hence, in this perturbed case, no guarantees of boundedness can be provided. In fact, it can be shown that if $\eta(t)$ is chosen in a particular manner, the closed-loop signals can actually be shown to become unbounded, either in the presence of bounded disturbances (Narendra and Annaswamy 2005) or with unmodeled dynamics (Rohrs et al. 1985). This in turn led to the area of robust adaptive control.

Various approaches that have been developed under the rubric of robust adaptive control can be grouped into two categories. The first of these is related to modifications in the adaptive laws so as to ensure boundedness. These changes consist of modifications in the adaptive law (3) as

$$\dot{\theta} = \text{sign}(\lambda) - \Gamma \omega b^T P e - \sigma g(\theta, e) \quad (25)$$

The problem then reduces to finding a suitable $g(\theta, e)$. This is discussed in detail in the next section. The second approach used in adaptive control pertains to the use of a persistently exciting reference signal r . The latter ensures parameter convergence of the adaptive system and therefore exponential stability. This in turn ensures robustness of the overall system. These details are addressed in section “[Robust Adaptive Control with Persistently Exciting Reference Input](#)”.

Robust Adaptive Control with Modifications in the Adaptive Law

Robustness to Bounded Disturbances

When a bounded input disturbance η is present, the plant dynamics is changed as

$$\dot{x}_p = A_p x_p + b\lambda(u + \eta(t)), \quad (26)$$

$$g(\theta, e) = \begin{cases} \theta & \text{Ioannou and Sun (2013)} \\ \|e\|\theta & \text{Narendra and Annaswamy (1987)} \\ \theta \left(1 - \frac{\|\theta\|}{\theta_{\max}}\right)^2 & \text{Kreisselmeier and Narendra (1982)} \end{cases} \quad (27)$$

where $\theta_{\max}$ is a known bound on the parameter θ . (One can choose to set σ to zero if $\|\theta\| \leq \theta_{\max}$, as is done in Ioannou and Sun (2013), Tsakalis and Ioannou (1987), and many other references in the literature.) An alternate approach that is different from (25) is to not have an additive term $g(\cdot, \cdot)$ but rather set $\dot{\theta} = 0$ whenever the error e is small in some sense. Such a dead zone approach was suggested, for example, in Egardt (1979) and Peterson and Narendra (1982). It can be shown that each one of these choices leads to boundedness, which is described below. Without loss of generality, we assume that $\lambda > 0$.

With the same Lyapunov function candidate as in (23), its time derivative now becomes

$$\dot{V} \leq -\frac{1}{2}e^T Q e + k_1 \|e\| \|\eta\| - k_2 \tilde{\theta}^T g(\theta, e), \quad (28)$$

for some $k_1, k_2 > 0$.

The property of $g(\cdot, \cdot)$, together with the fact that η is bounded, ensures that $\dot{V} < 0$ outside a compact set Ω in the $(e, \tilde{\theta})$ space. This ensures global boundedness of both e and $\tilde{\theta}$. Boundedness of x_p follows.

In all of the above methods, the idea behind adding the term $g(e, \theta)$ is this: the parameter θ can drift away from the correct direction due to the term $k_1 \|e\| \|\eta\|$, and the construction of

while the reference model and the controller remain the same as in (4) and (2), respectively. As mentioned above, a modification to the adaptive law as in (25) is needed. Over the years, different choices have been suggested for the nonlinear function $g(\theta, e)$. For example, these are chosen as

$g(e, \theta)$ is such that it counteracts this drift and keeps the parameter in check, by adding a negative quadratic term in $\tilde{\theta}$. The boundedness of both e and θ is simultaneously assured in the above since V has a time derivative $\dot{V}$ that is nonpositive outside a compact set in the $(e, \tilde{\theta})$ space. It should be noted however that this was possible to a large extent because η was bounded, and as a result, the sign-indefinite term remained linear in $\|e\|$.

An alternative procedure, originally proposed in Pomet and Praly (1992) and revised and refined in Khalil (2001) and Lavretsky (2011), proceeds in a slightly different manner. Here, the boundedness of θ is first established, independent of the error equation. It should be noted that a similar approach is adopted in the context of output feedback in plants with higher relative degree by using normalization and an augmented error approach (Narendra and Annaswamy 2005). In Khalil (2001) and Lavretsky (2011), no normalization is used but a projection algorithm. This is described below.

The projection algorithm for adjusting the parameter θ is given by

$$\dot{\theta} = \text{Proj}(\theta, y), \quad (29)$$

where

$$\text{Proj}(\theta, y) = \begin{cases} y - \frac{\nabla f(\theta)(\nabla f(\theta))^T}{\|\nabla f(\theta)\|^2} y f(\theta) & \text{if } [f(\theta) > 0 \wedge y^T \nabla f(\theta) > 0] \\ y & \text{otherwise} \end{cases} \quad (30)$$

$$y = -\text{sign}(\lambda)\omega b^T P e \quad (31)$$

$$f(\theta) = \frac{\|\theta\|^2 - \theta_{\max}^2}{\varepsilon^2 + 2\varepsilon\theta'_{\max}} \quad (32)$$

where $\theta'_{\max}$ and ε are arbitrary positive constants and Ω_0 and Ω_1 are defined as

$$\begin{aligned} \Omega_0 &= \{\theta \in \mathbb{R}^n | f(\theta) \leq 0\} \\ \Omega_1 &= \{\theta \in \mathbb{R}^n | f(\theta) \leq 1\}. \end{aligned} \quad (33)$$

From the above relations, one can show that

$$\theta(0) \in \Omega_0 \implies \theta(t) \in \Omega_1.$$

In addition,

$$\theta'_{\max} = \max_{\theta \in \Omega_0} (\|\theta\|), \quad \theta_{\max} = \max_{\theta \in \Omega_1} (\|\theta\|) \quad (34)$$

where $\theta_{\max} = \theta'_{\max} + \varepsilon$ (Matsutani et al. 2011).

Robustness to Unmodeled Dynamics

One of the major observations in the early 1980s was the stark difference between the system signals in the ideal adaptive system and the perturbed adaptive system when the perturbation was due to commonly present unmodeled dynamics such as those of an actuator used for control implementation. Among other references, the publication in Rohrs et al. (1985) pointed out the fact that when an adaptive controller prescribed for a first-order plant is evaluated with unmodeled dynamics present, instability occurs readily and for a wide range of command signals. A number of solutions have been suggested to alleviate this instability and form the subject matter of this section.

We consider the plant in (26) with an additional unmodeled dynamics so that

$$\begin{aligned} \dot{x}_p &= A_p x_p + b \lambda v \\ \dot{x}_\eta &= A_\eta x_\eta + b_\eta u, \quad v = \tilde{c}_\eta^T x_\eta. \end{aligned} \quad (35)$$

where A_η is a Hurwitz matrix. If $\eta = v - u$, then the plant dynamics can be rewritten as

$$\dot{x}_p = A_p x_p + b \lambda (u + \eta) \quad (36)$$

Unlike the bounded disturbance case, no upper bound d_0 can be assumed to exist as η is a state-dependent disturbance. It is this that causes a huge difference between deriving boundedness in section “[Robustness to Bounded Disturbances](#)” and here in section “[Robustness to Unmodeled Dynamics](#)”. Significant effort has been extended in the adaptive control community in this regard. These results fall into two categories (i) that assure global boundedness for a narrow class of unmodeled dynamics and (ii) that assure semi-global boundedness for a slightly larger class of unmodeled dynamics. More recently, some results have been obtained that are able to establish global boundedness with minimal restrictions on the unmodeled dynamics. In what follows, we give examples of each of the above two cases as well as the recent results.

Global Boundedness in the Presence of a Small Class of Unmodeled Dynamics

For the plant in (26), under assumptions in (5), the plant can be rewritten as

$$\dot{x} = A_m x + b \lambda (u + \theta_x^{*T} x + \eta) \quad (37)$$

where λ and θ_x^* are unknown, A_m and b are known, and $\eta = v - u$ whose state-space representation can be shown to be of the form

$$\dot{x}_\eta = A_\eta x_\eta + b_\eta u, \quad \eta = c_\eta^T x_\eta \quad (38)$$

for some vector c_η .

For a class of unmodeled dynamics $\{c_\eta, A_\eta, b_\eta\}$, if the control input in (2) and the projection algorithm in (29) with y and $f(\theta)$ chosen as in (31) and (32) are used, one can guarantee boundedness. In particular, if the inequality

$$k\theta_{x,\max}\lambda_{\max}\left(\frac{b_0}{\sigma_{A_\eta}}\right) < 1 \quad (39)$$

is satisfied, where b_0 is an upper bound on $\|b_\eta\|$ and σ_A denotes the singular value of the matrix A , then boundedness follows. That is, robustness of adaptive controllers can be ensured if the

unmodeled dynamics are fast and their zeros are restricted in some sense.

A specific example of such an unmodeled dynamics is given by

$$c_\eta^T (sI - A_\eta)^{-1} b_\eta = \frac{-2\mu s}{1 + \mu s} \quad (40)$$

for a given $\mu > 0$.

Global Boundedness for a Large Class of Unmodeled Dynamics: A First-Order Example

A different approach can be taken for the problem of unmodeled dynamics which allows a global result, for a class of adaptive systems (Hussain et al. 2013). The main idea here is to use the projection algorithm and use properties of adaptive systems in conjunction with linear time-varying systems. This is presented in this section using a first-order plant.

We consider the control of

$$\dot{x}_p(t) = a_p x_p(t) + k_p v(t) \quad (41)$$

where a_p is unknown and k_p is known. It is assumed that $|a_p| \leq \bar{a}$, where $\bar{a}$ is a known positive constant. The unmodeled dynamics is given by (38) with

$$G_\eta(s) \triangleq c_\eta^T (sI_{n \times n} - A_\eta)^{-1} b_\eta. \quad (42)$$

The goal is to design the control input such that $x_p(t)$ follows $x_m(t)$ which is specified by the reference model

$$\dot{x}_m(t) = a_m x_m(t) + k_m r(t) \quad (43)$$

where $a_m < 0$ and reference input is $r(t)$. The proposed adaptive controller is of the form

$$u(t) = \theta(t)x_p(t) + \frac{k_m}{k_p} r(t) \quad (44)$$

where the parameter $\theta(t)$ is updated using a projection algorithm of the form

$$\begin{aligned} \dot{\theta}(t) &= \gamma \text{Proj}(\theta(t), -x_p(t)(x_p(t) - x_m(t))), \\ \gamma &> 0 \end{aligned} \quad (45)$$

and

$$\text{Proj}(\theta, y) = \begin{cases} \frac{\theta_{\max}^2 - \theta^2}{\theta_{\max}^2 - \theta_{\min}^2} y & [\theta \in \Omega_A, y > 0] \\ y & \text{otherwise} \end{cases} \quad (46)$$

$$\Omega_0 = \{\theta \in \mathbb{R}^1 \mid -\theta'_{\max} \leq \theta \leq \theta'_{\max}\}$$

$$\Omega_1 = \{\theta \in \mathbb{R}^1 \mid -\theta_{\max} \leq \theta \leq \theta_{\max}\} \quad (47)$$

$$\Omega_A = \Omega_1 \setminus \Omega_0$$

with positive constants $\theta'_{\max}$ and $\theta_{\max}$ given by

$$\theta'_{\max} > \frac{\bar{a} + |a_m|}{k_p}, \quad \theta_{\max} = \theta'_{\max} + \varepsilon_0, \quad (48)$$

where ε_0 is an arbitrary positive constant. It can be shown that if $\theta_{\max}$ is chosen as in (48), then the closed adaptive system specified by Eqs. (41)–(48) always has guaranteed bounded solutions for a class of unmodeled dynamics $G_\eta(s)$. Additionally, there is an optimal value of ε_0 for which the largest class of $G_\eta(s)$ can be found.

It should be noted that in the Rohrs example in Rohrs et al. (1985), the plant is first order, with $a_p = -1$, and

$$G_\eta = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2}, \quad (49)$$

for $\zeta = 1$, $\omega_n = 15$. It is easy to show that for these values of ζ and ω_n , if $\theta_{\max} = 17$, then Eq. (48) is satisfied and that the closed-loop system is robust to G_η .

In general, for a first-order plant as in (41), it can be shown that the adaptive system is robust for G_η for all (ζ, ω_n) that satisfy the following inequalities for all $|a_p| \leq \bar{a}$:

$$\begin{aligned} -a_p \zeta^2 + f(a_p, \omega_n) \zeta - \frac{k_p \theta_{\max}}{4} &> 0 \\ \omega_n &> \omega_{n_{\min}} \end{aligned} \quad (50)$$

where

$$f(a_p, \omega_n) = \frac{a_p^2 + \omega_n^2}{2\omega_n}$$

$$\omega_{n_{\min}} = \max \left(\frac{\bar{a}}{2\zeta}, 2\zeta\bar{a}, \sqrt{\bar{a}k_p\theta_{\max}} \right. \\ \left. \left\{ 1 + \sqrt{1 - \frac{\bar{a}}{k_p\theta_{\max}}} \right\} \right) \quad (51)$$

When a time delay τ is present in the plant to be controlled, the plant under consideration can be represented as in (37) where

$$\eta(t) = u(t - \tau) - u(t).$$

Similar results of boundedness can be derived in this case as well (Matsutani 2013; Matsutani et al. 2012, 2013), with a comprehensive derivation available in Hussain et al. (2017).

Adaptive Control in the Presence of Magnitude Constraints on the Input

Physical plant models commonly have input magnitude constraints which need to be explicitly accounted for in the design of robust adaptive control systems. The first such results which design adaptive update laws for a general class of output feedback plants was described in Kárason and Annaswamy (1994). Similar to (8), consider the single-input single-output plant of the form

$$y_p(t) = W_p(s)u(t) = \left[k_p \frac{Z_p(s)}{R_p(s)} \right] u(t) \quad (52)$$

where the input $u(t)$ is subjected to a magnitude constraint as

$$|u(t)| \leq u_0, \quad u_0 > 0. \quad (53)$$

It is assumed that $Z_p(s)$ is Hurwitz and the sign of k_p , the order, and the relative degree of plant are all known. In the presence of magnitude saturation, the goal is for the plant output $y_p(t)$ to track a reference trajectory $y_m(t)$ which is

generated from

$$y_m(t) = W_m(t)r(t) = \left[k_m \frac{Z_m(s)}{R_m(s)} \right] r(t) \quad (54)$$

where $W_m(s)$ is designed to be asymptotically stable, minimum phase and with known relative degree n^* , similar to (10). Additionally the reference signal $r(t)$ is assumed to be piecewise-continuous and satisfy $|r(t)| \leq r_0$ for a finite $r_0 > 0$.

Then as in Kárason and Annaswamy (1994), the following controller modified from Eqs. (11), (12), (13), (14), and (15) may then be chosen:

$$\dot{\omega}_1(t) = \Lambda \omega_1(t) + b_\lambda u(t) \quad (55)$$

$$\dot{\omega}_2(t) = \Lambda \omega_2(t) + b_\lambda y_p(t) \quad (56)$$

$$\omega(t) = [r(t), \omega_1^T(t), y_p(t), \omega_2^T(t)] \quad (57)$$

$$\theta(t) = [k(t), \theta_1^T(t), \theta_0(t), \theta_2^T(t)] \quad (58)$$

$$v(t) = \theta^T(t)\omega(t) \quad (59)$$

$$u(t) = \begin{cases} v(t), & \text{if } |v(t)| \leq u_0 \\ u_0 \operatorname{sgn}(v(t)), & \text{if } |v(t)| > u_0 \end{cases} \quad (60)$$

where $\theta_1(t), \theta_2(t), \omega_1(t), \omega_2(t) \in \mathbb{R}^{n-1}$, $k(t), \theta_0(t) \in \mathbb{R}$, $b_\lambda \in \mathbb{R}^{n-1}$, and $\Lambda \in \mathbb{R}^{(n-1) \times (n-1)}$ is Hurwitz. The parameter estimation errors may then be stated as: $\psi(t) = k(t) - k^*$, $\phi_0(t) = \theta_0(t) - \theta_0^*$, $\phi_1(t) = \theta_1(t) - \theta_1^*$, $\phi_2(t) = \theta_2(t) - \theta_2^*$, $\phi(t) = [\psi(t), \phi_1^T(t), \phi_0(t), \phi_2^T(t)]^T$.

With the output tracking error defined as $e_1 = y_p - y_m$ and input disturbance given by the control deficiency defined as $\Delta u = u - v$, the error model may be stated as

$$e_1(t) = \frac{k_p}{k_m} W_m(s) [\phi^T(t)\omega(t) + \Delta u(t)]. \quad (61)$$

Given the additional disturbance term Δu in the error model, an additional signal is generated as

$$e_\Delta(t) = k_\Delta(t) W_m(s) \Delta u(t) \quad (62)$$

where $k_\Delta(t)$ is an additional parameter for which an adaptive law will be designed. Defining $e_{u1} =$

$e_1 - e_\Delta$:

$$e_{u1}(t) = \frac{1}{k^*} W_m(s) [\phi^T(t) \omega(t)] + \psi_\Delta(t) W_m(s) \Delta u(t) \quad (63)$$

with $\psi_\Delta(t) = \frac{1}{k^*} - k_\Delta(t)$. The auxiliary and augmented errors may then be defined as

$$e_2(t) = [\theta^T W_m(s) I - W_m(s) \theta^T(t)] \omega(t) \quad (64)$$

$$\varepsilon_{1u}(t) = e_{u1}(t) + k_1(t) e_2(t). \quad (65)$$

The adaptive update laws for this error model may then be stated of the form

$$\dot{\theta}(t) = \dot{\phi}(t) = -\text{sgn}(k_p) \frac{\varepsilon_{1u}(t) \xi(t)}{1 + \xi^T(t) \xi(t)} \quad (66)$$

$$\dot{k}_1(t) = \dot{\psi}_1(t) = -\frac{\varepsilon_{1u}(t) e_2(t)}{1 + \xi^T(t) \xi(t)} \quad (67)$$

$$\dot{k}_\Delta(t) = -\dot{\psi}_\Delta(t) = \frac{\varepsilon_{1u}(t) \xi_\Delta(t)}{1 + \xi^T(t) \xi(t)} \quad (68)$$

where $\xi(t) = W_m(t) I \omega(t)$, $\xi_\Delta(t) = W_m(s) \Delta u(t)$, $\psi_1(t) = k_1(t) - (1/k^*)$ (Káráson and Annaswamy 1994).

It can be noted that the additional components of the modified adaptive update laws directly account for the control deficiency Δu . Due to the constraints on the input, for general plant models $W_p(s)$, stability results are local in nature. If the plant $W_p(s)$ is asymptotically stable, then due to the presence of a saturated input, stability follows due to the bounded-input bounded-output property. For open-loop unstable plants, regions of attraction may be defined which are proportional to the level of saturation u_0 and upper bounds on the uncertainty of the system. It can be noted that for open-loop unstable plants, there always exist initial conditions for which the closed-loop system can be unstable, thus the need for derivations of regions of attraction as provided in Káráson and Annaswamy (1994).

Adaptive Augmentation of Robust Controllers

Commonly adaptive controllers are employed as augmentations to robust output feedback controllers. One such example which has been employed in aircraft flight platforms is the observer-based loop transfer recovery (OBLTR) method as described in Lavretsky and Wise (2013). Consider the open-loop plant model of the form

$$\begin{aligned} \dot{x}(t) &= Ax(t) + B\Lambda^* \left(u(t) + \Theta^{*T} \Phi(x(t)) \right) \\ &\quad + B_z z_{cmd}(t) \end{aligned} \quad (69)$$

$$y(t) = Cx(t) \quad (70)$$

where $A \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$, $B_z \in \mathbb{R}^{n \times n_z}$, and $C \in \mathbb{R}^{p \times n}$ are known dynamics, input, reference, and output matrices, respectively. The unknown diagonal positive definite input control effectiveness matrix is denoted as $\Lambda^* \in \mathbb{R}^{m \times m}$, and the unknown additive uncertainty is $\Theta^* \in \mathbb{R}^{N \times m}$. The additive uncertainty acts upon a known continuously differentiable regressor $\Phi(x(t)) \in \mathbb{R}^{N \times 1}$. It is assumed that the pair (A, B) is controllable and the pair (A, C) is observable. Given that this system is in an output feedback setting, a state observer, which will function additionally as a closed-loop reference model, is designed as

$$\dot{\hat{x}}(t) = A_m \hat{x}(t) + L_v (y(t) - \hat{y}(t)) + B_z z_{cmd}(t) \quad (71)$$

$$\hat{y}(t) = C \hat{x}(t) \quad (72)$$

where $A_m = A - BK_{LQR}^T$. A systematic loop transfer recovery-based procedure is provided by Lavretsky and Wise (2013) to design the state feedback gain $K_{LQR} \in \mathbb{R}^{n \times m}$ and observer gain $L_v \in \mathbb{R}^{n \times p}$.

The control input may then be selected as a combination of a robust output feedback contribution and adaptive augmentation as

$$u(t) = u_{bl}(t) + u_{ad}(t) \quad (73)$$

where $u_{bl}(t) = -K_{LQR}^T \hat{x}(t)$ is the robust baseline control contribution and $u_{ad}(t)$ is an adap-

tive augmentation. Based on the design of the output feedback robust baseline control $u_{bl}(t)$, Lavretsky and Wise (2013) provides a method to synthesize the adaptive input $u_{ad}(t)$ given the robust output feedback design parameters K_{LQR} , L_v and the known plant matrices.

Robustness Modifications to Track Time-Varying Parameters

Similar to the discussion in Narendra and Annaswamy (2005), a scalar plant of the following form will be considered to elucidate the essential problem of tracking time-varying parameters:

$$\dot{x}_p(t) = a_p(t)x_p(t) + u(t) \quad (74)$$

where $a_p(t)$ is the unknown time-varying parameter. The reference model for the plant to track is of the form

$$\dot{x}_m(t) = a_m x_m(t) + r(t) \quad (75)$$

where $a_m < 0$ and $r(t)$ is a selected reference input. The control input is chosen as

$$u(t) = \theta(t)x_p(t) + r(t). \quad (76)$$

With a model tracking error $e = x_p - x_m$, the error model is of the form

$$\dot{e}(t) = a_m e(t) + (a_p(t) + \theta(t) - a_m(t))x_p(t). \quad (77)$$

If $a_p(t)$ were to be known, then the parameter estimate could be chosen as $\theta(t) = \theta^*(t)$, with $\theta^*(t) = a_m - a_p(t)$. Such a choice of $\theta(t)$ would result in model tracking with $\lim_{t \rightarrow \infty} e(t) = 0$. Given however that $a_p(t)$ (and thus $\theta^*(t)$) is unknown, an adaptive update law must be designed using available input-output data to achieve model tracking. The time-varying nature of the unknown parameter requires additional assumptions regarding the time variation in order to arrive at a tractable problem statement. One such assumption regarding the time variation is bounded magnitude and time derivative of the unknown parameter, i.e., $|a_p(t)| \leq a_0$ and $|\dot{a}_p(t)| \leq d_0$.

With a parameter error $\phi(t) = \theta(t) - \theta^*(t)$ and standard adaptive law $\dot{\theta} = -e x_p$, the model tracking and parameter error equations may be expressed of the form

$$\begin{aligned} \dot{e}(t) &= a_m e(t) + \phi(t)x_p(t) \\ \dot{\phi}(t) &= -e(t)x_p(t) - \dot{\theta}^*(t) \end{aligned} \quad (78)$$

It can be noted that (78) is nonlinear and nonautonomous, and due to the presence of $\dot{\theta}^*(t)$, additional modifications are necessary to ensure boundedness of $e(t)$ and $\phi(t)$. One such modification is the sigma-modification (Ioannou and Sun 2013) in (27) for which the adaptive law is then of the form

$$\dot{\phi}(t) = -e(t)x_p(t) - \sigma\theta(t) - \dot{\theta}^*(t) \quad (79)$$

where $\sigma > 0$ is a user-designed parameter. A Lyapunov function $V(e(t), \phi(t)) = e^2(t) + \phi^2(t)$ can be employed to yield a time derivative $\dot{V}(e(t), \phi(t))$ which is negative definite outside of a compact region in the (e, ϕ) space containing the origin (Narendra and Annaswamy 2005).

Robust Adaptive Control with Persistently Exciting Reference Input

We return to the plant in (26) with the control input as in (2) and the adaptive law as in (3). When $\eta(t)$ is bounded with a finite upper bound d_0 , it can be shown that no modifications are necessary in the adaptive law to ensure boundedness if the reference input is persistently exciting. It can be shown that if the reference input $r(t)$ is such that the vector ω^* defined as $\omega^* = [x_m^T, r]^T$ is persistently exciting with

$$\left| \frac{1}{T} \int_t^{t+T} \omega^{*T}(\tau) w d\tau \right| \geq k d_0 \quad \forall t \geq t_0$$

for every unit vector $w \in \mathbb{R}^n$, where $k > 0$, T are finite constants, then the adaptive system is well behaved, i.e., has globally bounded solutions (Narendra and Annaswamy 2005).

An alternative approach for achieving robustness has been addressed in Anderson et al. (1986) that addresses local stability in the presence of persistently exciting signals. The starting point for this investigation is (35) but when not all states are accessible. Assuming that an output $y = c_p^T x_p$ is measurable and a controller as in (11), (12), (13), (14), and (15) and a reference model as in (10) are used, the underlying error equation can be written as

$$e_1 = \bar{W}_m(s) (\tilde{\theta}^T \omega + \bar{v}) \quad (80)$$

where $\bar{W}_m(s)$ is asymptotically stable, $\tilde{\theta}$ is the parameter error vector, and $\bar{v}$ is the effect of the unmodeled dynamics η at the input. Suppose the standard adaptive law is used and as a first step, the perturbation $\bar{v}$ is ignored, the underlying error equation and the adaptive law are given by

$$e_1 = \bar{W}_m(s) \tilde{\theta}^T \omega \quad (81)$$

$$\dot{\tilde{\theta}} = -\mu e_1 \omega, \quad \mu > 0. \quad (82)$$

If the origin in the $(e_1, \tilde{\theta})$ space of (81) and (82) is exponentially stable, all solutions of (80) are bounded for sufficiently small initial conditions and $\bar{v}(t)$. Therefore, the question that is of interest is the set of conditions of persistent excitation that will assure such an exponential stability. This is addressed in Anderson et al. (1986). The underlying tool is the method of averaging (Krylov and Bogoliuboff 1943; Hale 1969; Arnold 1988) used in the study of nonlinear oscillations and addresses the stability property of the differential equation

$$\dot{x} = \mu f(x, t, \mu), \quad x(0) = x_0 \quad (83)$$

where μ is a small parameter. By a process of averaging, the nonautonomous system in (83) is approximated by an autonomous differential equation in x_{av} , an averaged value of x . This autonomous system, which is easier to analyze, can be used to derive stability properties of (83).

In order to use the method of averaging for robust adaptive control, we write Eqs. (81) and (82) as

$$\begin{bmatrix} \dot{e} \\ \dot{\tilde{\theta}} \end{bmatrix} = \begin{bmatrix} A & b\omega^T \\ -\mu\omega h^T & 0 \end{bmatrix} \begin{bmatrix} e \\ \tilde{\theta} \end{bmatrix} \quad (84)$$

Theorem 1 *Let $\omega(t)$ be bounded, almost periodic, and persistently exciting. Then there exists a $c^* > 0$ such that for all $\mu \in (0, c^*]$, the origin of (84) is exponentially stable if*

$$\Re \left[\lambda_i \left(\int_0^T \omega(t) \bar{W}_m(s) \omega^T(t) dt \right) \right] > 0, \quad \forall i = 1, \dots, n \quad (85)$$

and is unstable if

$$\Re \left[\lambda_j \left(\int_0^T \omega(t) \bar{W}_m(s) \omega^T(t) dt \right) \right] < 0, \quad \text{for some } j = 1, \dots, n \quad (86)$$

In Kokotovic et al. (1985), it is further shown that $\omega(t)$ can be expressed as $\omega(t) = \sum_{k=-\infty}^{\infty} \Omega(iv_k) \exp(iv_k t)$, and the inequality in (85) can be satisfied if the condition

$$\sum_{k=-\infty}^{\infty} \Re [\bar{W}_m(iv_k)] \Re [\Omega(iv_k) \bar{\Omega}^T(iv_k)] > 0 \quad (87)$$

is satisfied, where $\bar{\Omega}(iv_k)$ is the complex conjugate of $\Omega(iv_k)$. Given a general transfer function $\bar{W}_m(s)$, there exists a large class of functions ω that satisfies (87), even when $\bar{W}_m(s)$ is not SPR.

ω in Theorem 1 is not an independent variable but rather an internal variable of the nonlinear system in (84). Hence, it cannot be shown to be bounded or persistently exciting. If ω_* represents the signal corresponding to ω in the reference model, it can be made to satisfy (85) by the proper choice of the reference input. Expressing $\omega = \omega_* + \omega_e$, ω will also be bounded, persistently exciting, and satisfy (85) if ω_e is small. This can be achieved by choosing the initial conditions $e(t_0)$ and $\tilde{\theta}(t_0)$ in (84) to be sufficiently small. The conditions of Theorem 1 are then verified, and for a sufficiently small μ , exponential stability of the origin of (84) follows.

Theorem 1 provides conditions for exponential stability and instability when the solutions of the adaptive system are sufficiently close to the tuned solutions. These are very valuable in understanding the stability and instability mechanisms peculiar to adaptive control in the presence of different types of perturbations. Many of these results have been summarized and presented in a unified fashion in Anderson et al. (1986).

Robust Control in Gap Metric

Li Qiu¹ and Di Zhao²

²Department of Electronic and Computer Engineering, Hong Kong University of Science and Technology, Hong Kong SAR, China

Abstract

Robust control needs to start with a model of system uncertainty. What is a good uncertainty model? First it needs to capture the

possible system perturbations and uncertainties. Second it needs to be mathematically tractable. The gap metric was introduced by Zames and El-Sakkary for this purpose. Its study climaxed in an award-winning paper by Georgiou and Smith. A modified gap, called the ν -gap, was later discovered by Vinnicombe and was shown to have advantages. When the plant and controller communicate through a non-ideal bidirectional channel, cascaded two-port networks can be utilized to model such a channel whose uncertainties are measured by the $\mathcal{H}_\infty$ norm. With these descriptions of uncertainties in hand, robust stabilization issues can be nicely addressed.

Gap metric · H-infinity control · ν -gap metric · Robust stabilization · Uncertain system · Networked control system · Two-port network

Introduction

The gap is rooted in mathematical literature for the purpose of measuring the distance between unbounded operators (Kato 1976). It is introduced to control theory by Zames and El-Sakkary (1980) to measure the distance between systems and subsequently to model an uncertain system, with the recognition that a possibly unstable system is simply a possibly unbounded operator. Here only continuous-time systems will be treated. Discrete-time systems can be treated in an analogous way. Let us identify a linear time-invariant (LTI) system with its transfer function. The set of m -input p -output finite-dimensional LTI systems is then identified with the set $\mathcal{R}^{p \times m}$ of $p \times m$ real rational matrices. Such a system can be considered as a linear operator from input space $\mathcal{H}_2^m$ to output space $\mathcal{H}_2^p$, defined by the input-output relation $y = Pu$. Here $\mathcal{H}_2$ is the collection of all bounded-energy signals $x(s)$ satisfying

$$\|x\|_2 := \sup_{\sigma > 0} \left(\frac{1}{2\pi} \int_{-\infty}^{\infty} |x(\sigma + j\omega)|^2 d\omega \right)^{1/2} < \infty.$$

This operator is possibly unbounded since for an input $u \in \mathcal{H}_2^m$, the corresponding output $y = Pu$ is not necessarily in $\mathcal{H}_2^p$. It is bounded if and only if P is stable, i.e., if and only if $P \in \mathcal{RH}_\infty^{p \times m}$, the set of $p \times m$ real rational matrices bounded over $\text{Re } s > 0$. In this case, the induced operator norm is the $\mathcal{H}_\infty$ norm of P :

$$\|P\|_\infty = \sup_{\text{Re } s > 0} \bar{\sigma}[P(s)] = \sup_{\omega \in \mathbb{R}} \bar{\sigma}[P(j\omega)].$$

No matter whether or not P is stable, we define the graph of P as

$$\mathcal{G}_P = \left\{ \begin{bmatrix} u \\ y \end{bmatrix} \in \mathcal{H}_2^{m+p} : y = Pu \right\},$$

i.e., the graph is the set of all finite energy input-output pairs. It is easy to see that $\mathcal{G}_P$ is a linear subspace of $\mathcal{H}_2^{m+p}$, and a little more effort shows that it is closed. Hence it uniquely corresponds to a bounded linear operator on $\mathcal{H}_2^{m+p}$, called the orthogonal projection onto $\mathcal{G}_P$, denoted by $\Pi_{\mathcal{G}_P}$. Now with two systems $P_1, P_2 \in \mathcal{R}^{p \times m}$, the gap in between is defined as

$$\delta(P_1, P_2) = \|\Pi_{\mathcal{G}_{P_1}} - \Pi_{\mathcal{G}_{P_2}}\|.$$

That the gap is a metric in $\mathcal{R}^{p \times m}$ follows from the fact that the induced operator norm used above defines a metric on the set of all orthogonal projections.

With the gap between two systems, an uncertain system described by the gap is simply a gap metric ball with a center P , called the nominal system, and a radius r , qualifying the amount of uncertainty:

$$\mathcal{B}(P, r) = \{\tilde{P} \in \mathcal{R}^{p \times m} : \delta(\tilde{P}, P) < r\}.$$

Gap Computation and Robust Stabilization

With the basic definitions constructed above, the following questions are then asked:

Computation: How can the gap between two systems be computed?

Analysis: How much stability robustness does a stable feedback system have against gap uncertainty in the plant or in both the plant and the controller?

Synthesis: How can a feedback controller be designed so that the feedback system has optimal robustness against gap uncertainty?

For the question on computation, it is rather easy to see that if P_1 and P_2 are static, also said to be memoryless, systems, i.e., $P_1(s) = K_1$ and $P_2(s) = K_2$, then

$$\delta(P_1, P_2) = \bar{\sigma}[(I + K_1 K_1^T)^{-1/2}(K_1 - K_2)(I + K_2^T K_2)^{-1/2}].$$

In the single-input single-output case, this is exactly the chordal distance between two numbers K_1 and K_2 . Hence the expression above generalizes the chordal distance between two complex numbers to constant matrices. What if P_1 and P_2 are dynamic systems? It is not until (Georgiou 1988) when the computation of the gap was settled by using the coprime factorization.

For each $P \in \mathcal{R}^{p \times m}$, there are

$$\begin{bmatrix} \tilde{V} & -\tilde{U} \\ -\tilde{N} & \tilde{M} \end{bmatrix}, \begin{bmatrix} M & U \\ N & V \end{bmatrix} \in \mathcal{RH}_\infty^{(m+p) \times (m+p)}$$

such that $P = NM^{-1} = \tilde{M}^{-1}\tilde{N}$ and

$$\begin{bmatrix} \tilde{V} & -\tilde{U} \\ -\tilde{N} & \tilde{M} \end{bmatrix} \begin{bmatrix} M & U \\ N & V \end{bmatrix} = \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix}.$$

These matrices are said to give a doubly coprime factorization of P . Also $P = NM^{-1}$ and $P = \tilde{M}^{-1}\tilde{N}$ are said to be right and left coprime factorizations, respectively. In the doubly coprime factorization, we can further require

$$M^T(-s)M(s) + N^T(-s)N(s) = I \text{ and} \\ \tilde{M}(s)\tilde{M}^T(-s) + \tilde{N}(s)\tilde{N}^T(-s) = I.$$

In this case, the coprime factorizations are said to be normalized.

Theorem 1 (Computation of the gap) Let $P_i = N_i M_i^{-1}$, $i = 1, 2$, be normalized right coprime factorizations. Then

$$\delta(P_1, P_2) = \max \{\delta(P_1, P_2), \delta(P_2, P_1)\},$$

where

$$\delta(P_1, P_2) = \inf_{Q \in \mathcal{RH}_\infty^{m \times m}} \left\| \begin{bmatrix} M_1 \\ N_1 \end{bmatrix} - \begin{bmatrix} M_2 \\ N_2 \end{bmatrix} Q \right\|_\infty.$$

The problems of finding the two infima above are $\mathcal{H}_\infty$ model-matching problems, special forms of $\mathcal{H}_\infty$ control problems. See article ► [“Optimal Control via Factorization and Model Matching”](#) and article ► [“H-Infinity Control”](#) in this encyclopedia. In principle, they can be solved using the standard ways.

The analysis and synthesis questions are satisfactorily answered by Georgiou and Smith (1990). Let us consider the feedback system shown in Fig. 1.

Such a feedback system is denoted by a plant and controller pair or simply a feedback pair $P \# C$ with $P \in \mathcal{R}^{p \times m}$ and $C \in \mathcal{R}^{m \times p}$. This closed-loop system is stable if the transfer matrix from $\begin{bmatrix} w_1 \\ -w_2 \end{bmatrix}$ to $\begin{bmatrix} u_1 \\ y_2 \end{bmatrix}$, nicknamed the Gang of Four matrix by Åström and Murray (2008),

$$P \# C = \begin{bmatrix} (I + PC)^{-1} & (I + PC)^{-1}C \\ C(I + PC)^{-1} & P(I + PC)^{-1}C \end{bmatrix} \\ = \begin{bmatrix} I \\ P \end{bmatrix} (I + PC)^{-1} \begin{bmatrix} I & C \end{bmatrix}$$

is stable. Here $P \# C$ denotes both the feedback system and its Gang of Four matrix.

Theorem 2 (Stability margin) Assume $P \# C$ is a stable closed-loop system. All feedback systems $\tilde{P} \# C$ with $\tilde{P} \in \mathcal{B}(P, r)$ are stable if and only if $r \leq \|P \# C\|_\infty^{-1}$.

It follows from Theorem 2 that $\|P \# C\|_\infty^{-1}$ is the stability margin of the closed-loop system in Fig. 1. The natural design problem is

Robust Control in Gap Metric, Fig. 1 An uncertain feedback system

then to design a controller C for a given P such that $\|P \# C\|_{\infty}^{-1}$ is maximized or equivalently $\|P \# C\|_{\infty}$ is minimized. Such a problem again is an $\mathcal{H}_{\infty}$ control problem, which is the topic of article ▶ “[H-Infinity Control](#)” in this encyclopedia. It is realized by Georgiou and Smith (1990) that this particular $\mathcal{H}_{\infty}$ control problem has some unique features. Let P have a normalized doubly coprime factorization, and let

$$R(s) = M^T(-s)U(s) + N^T(-s)V(s).$$

Then

$$\inf_C \|P \# C\|_{\infty} = \left(1 + \inf_{Q \in \mathcal{RH}_{\infty}^{m \times p}} \|R - Q\|_{\infty} \right)^{1/2}.$$

The minimization over Q above is a one-block $\mathcal{H}_{\infty}$ model-matching problem. It can be solved rather easily, much more easily than the $\mathcal{H}_{\infty}$ model-matching problem arising in the computation of gap. After finding an optimal Q , an optimal controller is obtained as

$$C = -(U - MQ)(V - NQ)^{-1}.$$

Qiu and Davison (1992a) extended Theorem 2 to the case when both the plant and controller are subject to uncertainty.

Theorem 3 (The arcsin theorem) Assume $P \# C$ is a stable closed-loop system. All feedback systems $\tilde{P} \# \tilde{C}$ with $\tilde{P} \in \mathcal{B}(P, r_P)$ and $\tilde{C} \in \mathcal{B}(C, r_C)$ are stable if and only if

$$\arcsin r_P + \arcsin r_C \leq \arcsin \|P \# C\|_{\infty}^{-1}.$$

This theorem further strengthens the role of $\|P \# C\|_{\infty}^{-1}$ as the robust stability margin of the feedback system $P \# C$.

The ν -Gap

Partly because of the lack of efficient ways in computing the gap, there were efforts in seeking other metrics on $\mathcal{R}^{p \times m}$ with better numerical and analytical properties. Several such metrics were proposed, including the graph metric by Vidyasagar (1984), pointwise gap metric by Qiu and Davison (1992b), and ν -gap metric by Vinnicombe (1993). The winner is the ν -gap which is defined by ingeniously exploring the special structures and properties of rational matrices in $\mathcal{R}^{p \times m}$. For $P_1, P_2 \in \mathcal{R}^{p \times m}$, let $P_i = N_i M_i^{-1}$, $i = 1, 2$, be normalized right coprime factorizations. Define the ν -gap metric as

$$\delta_{\nu}(P_1, P_2) = \sup_{\omega \in \mathbb{R}} \bar{\sigma} \left\{ [I + P_1(j\omega)P_1(j\omega)^*]^{-1/2} [P_1(j\omega) - P_2(j\omega)][I + P_2(j\omega)^*P_2(j\omega)]^{-1/2} \right\}$$

if $\det[M_2^T(-s)M_1(s) + N_2^T(-s)N_1(s)]$ has equal number of unstable poles and zeros and $\delta_{\nu}(P_1, P_2) = 1$ otherwise. Apparently ν -gap is easier to compute than the gap. When the pole-zero number condition is satisfied, the ν -gap is the peak of the chordal distance between the system frequency responses. The ν -gap is no greater than the gap, i.e.,

$$\delta_{\nu}(P_1, P_2) \leq \delta(P_1, P_2).$$

Hence the ν -gap ball

$$\mathcal{B}_{\nu}(P, r) = \{\tilde{P} \in \mathcal{R}^{p \times m} : \delta_{\nu}(\tilde{P}, P) < r\}$$

is a superset of the gap ball with the same center and radius. Theorems 2 and 3 can be restated with the gap balls $\mathcal{B}$ replaced by the new gap balls $\mathcal{B}_{\nu}$. Consequently the restated Theorems 2 and 3 are less conservative than the original versions for the gap. The optimal robust stabilization problems

Robust Control in Gap Metric, Fig. 2 An uncertain cascaded two-port networked control system

for the gap and the ν -gap are the same: design C to maximize $\|P \# C\|_{\infty}^{-1}$ for a given P .

Networked Robust Stabilization

In the era of network, a feedback system is expected to incorporate communication networks that are typically noisy and uncertain. Recently, two-port networks are adopted to model a bidirectional communication channel between the plant and controller in Zhao et al. (2020). As shown in Fig. 2, a networked control system (NCS) is described as a feedback interconnection of a plant P and a controller C communicating through a bidirectional channel modeled by cascaded two-port networks $\{T_k\}_{k=1}^l$. This model is sufficiently rich to capture various properties of a real-world communication channel subject to distortions, interferences, and even malicious attacks.

The network T in Fig. 3 has two external ports, with one port composed of signals u, y and the other of signals v, w . Naturally, we regard u, v as the downlink signals both with dimension m and w, y as the uplink signals both with dimension p . We describe a two-port network with its transmission (representation) matrix defined as

$$T = \begin{bmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{bmatrix} \in \mathcal{R}^{(m+p) \times (m+p)} \quad \text{and} \quad \begin{bmatrix} v \\ w \end{bmatrix} = T \begin{bmatrix} u \\ y \end{bmatrix}.$$

Here T stands for both the two-port network itself and its transmission matrix. It is worth noting that the transmission representation of a two-port network is also called the chain-scattering representation and has been used to solve the $\mathcal{H}_{\infty}$ control problems by Kimura (1996).

Robust Control in Gap Metric, Fig. 3 A two-port network T

When a two-port network describes ideal communication, it admits an identity transmission matrix; i.e.,

$$T = \begin{bmatrix} I_m & 0 \\ 0 & I_p \end{bmatrix}.$$

When a two-port network admits both distortions and interferences, its transmission matrix can be modeled by

$$T = I + \Delta = \begin{bmatrix} I_m + \Delta_{\div} & \Delta_{-} \\ \Delta_{+} & I_p + \Delta_{\times} \end{bmatrix},$$

$$\text{where } \Delta = \begin{bmatrix} \Delta_{\div} & \Delta_{-} \\ \Delta_{+} & \Delta_{\times} \end{bmatrix} \in \mathcal{RH}_{\infty}^{(m+p) \times (m+p)}.$$

The four-block matrix Δ is called the uncertainty quartet. The subscripts $+, -, \times, \div$ for Δ , which represent different types of uncertainties, were firstly used by Halsey and Glover (2005) for the purpose to describe various connections of uncertainties vividly.

The stability of an NCS is defined as usual. The two-port NCS in Fig. 2 is said to be stable if for all injected energy-bounded exogenous signals, the endogenous signals are energy-bounded. A necessary and sufficient robust stability condition of the two-port NCS was obtained by Zhao et al. (2020), which is a generalization of Theorem 3.

Theorem 4 (The information constrained arcsin theorem) Assume $P \# C$ is a stable

closed-loop system. For $r_P, r_C, r_k \in [0, 1)$, the NCS in Fig. 2 is stable for all $\tilde{P} \in \mathcal{B}(P, r_P)$, $\tilde{C} \in \mathcal{B}(C, r_C)$ and $\Delta_k \in \mathcal{RH}_\infty^{(m+p) \times (m+p)}$ with $\|\Delta_k\|_\infty \leq r_k, k = 1, 2, \dots, l$, if and only if

$$\arcsin r_P + \arcsin r_C + \sum_{k=1}^l \arcsin r_k < \arcsin \|P \# C\|_\infty^{-1}.$$

Clearly, the above theorem reduces to Theorem 3 when $r_k = 0, k = 1, 2, \dots, l$. It is noteworthy that when the gap balls in the above theorem are replaced by the ν -gap balls, the robust stability condition is still valid.

Summary and Future Directions

The gap, as well as the ν -gap, and the associated robust control theory can be extended to infinite dimensional systems as in Georgiou and Smith (1992) and Ball and Sasane (2012); time-varying systems as in Foias et al. (1993) and Feintuch (1998); and even nonlinear systems as in Georgiou and Smith (1997), Anderson et al. (2002), James et al. (2005), and Bian and French (2005), in varying degrees. There are still research opportunities in these extensions. The use of normalized coprime factorizations seems to be an obstacle in these extensions.

For a plant P , the controller optimizing $\|P \# C\|_\infty$ is not always a good controller. This gives another example where “optimal” is not always equal to “good.” One reason is that the actual plant uncertainty cannot necessarily be well described by a gap ball or a ν -gap ball. Another reason is that performance issues other than the stability robustness, such as tracking and disturbance rejection, are not taken into account in the optimization. The actual plant uncertainty might be better described by a gap ball centered at a frequency-shaped plant $\tilde{P} = W_o P W_i$ where W_i and W_o are real rational weighting matrices which can also be chosen to address tracking and disturbance rejection requirements. In this case, an optimal controller $\tilde{C}$ can then be designed to

optimize the transfer matrix $\tilde{P} \# \tilde{C}$ corresponding to the shaped plant $\tilde{P}$. Finally $C = W_i \tilde{C} W_o$ is used as a designed controller for the original plant P . With the proper choice of W_i and W_o , it is more likely that a good controller will result. This loop-shaping design method was proposed in McFarlane and Glover (1992) and further developed in Vinnicombe (2001).

In the process of obtaining the arcsin theorems for standard closed-loop systems and two-port NCSs, it has been realized that the gap and even more so the ν -gap are closely related to the canonical angles between linear subspaces. In fact the gap is the sin of the largest canonical angle between certain subspaces, and the largest canonical angle itself is also a metric, a better one in some geometric sense. For the latest development on canonical angles, see Qiu et al. (2008) and Zhang and Qiu (2010).

In addition to the effort in deepening and expanding the notion of gap and its use in robust control, there is also effort in making it more accessible and more closely related to classical frequency response analysis; see Qiu and Zhou (2013) and Zhao et al. (2018). It again appears that the use of coprime factorizations in the current theory is hindering this effort. Hence, circumventing the use of coprime factorizations, normalized or not, in the development of the gap would help its extension and popularization.

Recommended Reading

The most authoritative work on gap, ν -gap, and the associated robust stabilization theory is the

comprehensive monograph (Vinnicombe 2001). This theory is inherently an input-output frequency domain theory. However many related computations, such as those of doubly normalized coprime factorizations, $\mathcal{H}_\infty$ model matching, and the optimal controller synthesis, can be done using state-space formulas and further using MATLAB programs. Vinnicombe (2001) contains a list of such state-space formulas. This theory provides a good example of the once popular and successful philosophy behind the linear multivariable control theory: thinking in terms of transfer functions and computing in term of state-space equations.

The system and control background needed to understand and study the gap, the ν -gap, and robust stabilization, in particular the coprime factorization and frequency domain stabilization theory, can be found in Vidyasagar (1985).

The book Zhou and Doyle (1998) also contains considerable content on gap based robust control.

Robust Control of Infinite-Dimensional Systems

Hitay Özbay

Department of Electrical and Electronics
Engineering, Bilkent University, Ankara, Turkey

Abstract

Basic robust control problems are studied for the feedback systems where the underlying plant model is infinite dimensional. The $\mathcal{H}_\infty$ optimal controller formula is given for the mixed sensitivity minimization problem with rational weights. Key steps of the numerical computations required to determine the controller parameters are illustrated with an example where the plant model includes time delay terms.

Coprime factorizations · Direct design methods · Inner-outer factorizations

Introduction

Robust control deals with the feedback system shown in Fig. 1, where P_Δ represents the uncertain physical plant and C is a fixed controller to be designed.

Here, it is assumed that the controller and the plant are linear time-invariant (LTI) systems and they are represented by their transfer functions. Furthermore, P_Δ satisfies the following conditions:

$$P_\Delta(s) = P(s) + \Delta(s)$$

where P is the nominal plant model, with $P(s)$ and $P_\Delta(s)$ having the same number of poles in $\mathbb{C}_+$; and there is a known uncertainty bound $W(s)$ satisfying

$$|\Delta(j\omega)| < |W(j\omega)| \quad \forall \omega \in \mathbb{R}.$$

Robust Control of Infinite-Dimensional Systems, Fig. 1 Feedback system $\mathcal{F}(C, P_\Delta)$ with fixed controller C and uncertain plant P_Δ

Definition 1 All P_Δ satisfying the above conditions are said to be in the set of uncertain plants $\mathcal{P}$, which is characterized by the given functions $P(s)$ and $W(s)$.

Depending on physical system modeling, other forms of uncertainty representations can be more convenient than the additive unstructured uncertainty model taken here; see, e.g., Doyle et al. (1992), Özbay (2000), and Zhou et al. (1996) for the examples of multiplicative, coprime factor, parametric, and structured uncertainty descriptions. Note that for notational convenience and simplicity of the presentation, single-input-single-output (SISO) plants are considered here; for extensions to multi-input-multi-output (MIMO) plants, see, e.g., Curtain and Zwart (1995).

When the plant under consideration is infinite dimensional, the transfer function $P(s)$ is irrational, i.e., it cannot be expressed as a ratio of two polynomials (it does not admit a finite-dimensional state-space representation). Typical examples of such systems are spatially distributed parameter systems modeled by partial differential equations, fractional-order systems, and systems with time delays. The reader is referred to Curtain and Morris (2009) for examples of transfer functions of distributed parameter systems. There are many interesting industrial applications where fractional-order transfer functions are used for modeling and control, see, e.g., Monje et al. (2010); typically, such functions are rational in s^α , where α is a rational number in the open interval $(0, 1)$. Transfer functions of systems with time delays involve terms like e^{-hs} where $h > 0$ is the delay; see Sipahi et al. (2011) for various real-life examples where time-delay mod-

els appear. Transfer functions considered here are functions of the complex variable s with real coefficients, so $\overline{P(\bar{s})} = P(s)$ where $\bar{s}$ denotes the complex conjugate of s .

Definition 2 A linear time-invariant system H is said to be *stable* if its transfer function $H(s)$ is bounded and analytic in $\mathbb{C}_+$. In this case, the *system norm* is

$$\|H\| = \|H\|_\infty = \sup_{\operatorname{Re}(s) > 0} |H(s)|,$$

which is equivalent to the *energy amplification* through the system H ; see Doyle et al. (1992) and Foias et al. (1996).

Definition 2 is sometimes called the $\mathcal{H}_\infty$ -stability, and in this setting, the set of all stable plants is the function space $\mathcal{H}_\infty$. It is worth noting that for infinite-dimensional systems, there are other definitions of stability (Curtain and Zwart 1995; Desoer and Vidyasagar 2009), leading to different measures of the system norm.

Robust Control Design Objectives

Let $\mathcal{F}(C, P_\Delta)$ denote the feedback system shown in Fig. 1. This system is said to be *robustly stable* if all the transfer functions from external inputs (r, v) to internal signals (e, u) are in $\mathcal{H}_\infty$ for all $P_\Delta \in \mathcal{P}$. In the controller design, robust stability of the feedback system is the primary constraint.

The feedback system $\mathcal{F}(C, P_\Delta)$ is robustly stable if and only if the following conditions hold; see, e.g., Doyle et al. (1992) and Foias et al. (1996),

$$(a) \quad S, CS, PS \in \mathcal{H}_\infty, \text{ where } S = (1 + PC)^{-1},$$

and

$$(b) \quad \|WCS\|_\infty \leq 1.$$

In order to illustrate these design constraints for robustly stabilizing controller, as an example, consider a strictly proper stable plant, i.e.,

$$P \in \mathcal{H}_\infty \quad \text{with} \quad \lim_{|s| \rightarrow \infty} |P(s)| = 0.$$

In this case, all controllers in the form $C = Q/(1 - PQ)$ satisfy condition (a) for any $Q \in \mathcal{H}_\infty$ (moreover, any controller C satisfying (a) must be in this form for some $Q \in \mathcal{H}_\infty$). Now consider a rational $W(s)$ with a stable Q such that $|Q(j\omega)|$ is a continuous function of $\omega \in \mathbb{R}$. Then, condition (b) becomes

$$\|WQ\|_\infty \leq 1 \iff |Q(j\omega)| \leq |W(j\omega)|^{-1} \quad \forall \omega \in \mathbb{R}.$$

So, whenever the modeling uncertainty is “large” on a frequency band $\omega \in \Omega$, the magnitude of Q should be “small” in this region.

When the plant is unstable, say $p \in \mathbb{C}_+$ is a pole of $P(s)$ of multiplicity one, conditions (a) and (b) impose a restriction on the controller, which leads to

$$1 \geq \|WCS\|_\infty \geq \left| \frac{W(p)}{N(p)} \right| \quad \text{where } N(p) = \lim_{s \rightarrow p} \frac{(s - p)}{(s + \bar{p})} P(s).$$

So, a necessary condition, for (b) to hold in this case, is $|W(p)| \leq |N(p)|$, which means that the modeling uncertainty at the unstable pole of the plant should be small enough for the existence of a robustly stabilizing controller. This is one of the fundamental quantifiable limitations of feedback systems with unstable plants; see Stein (2003) for further discussions on other limitations.

Many other performance-related design objectives, such as reference tracking and disturbance attenuation, are captured by the *sensitivity minimization*, which is defined as finding a controller satisfying (a) and achieving

$$(c) \quad \|W_1 S\|_\infty \leq \gamma$$

for the smallest possible $\gamma > 0$, for a given stable sensitivity weight $W_1(s)$. Selection of W_1 depends on the class of reference signals and disturbances considered; see Doyle et al. (1992), Özbay (2000), and Stein (2003) for general guidelines. Stability robustness and performance objectives defined above can be

blended to define a single $\mathcal{H}_\infty$ -optimization problem, known as the *mixed sensitivity minimization*: given W_1 , W_2 , P , find a controller C satisfying (a) and achieving

$$(d) \left\| \begin{bmatrix} W_1 S \\ W_2 T \end{bmatrix} \right\|_\infty := \sup_{\operatorname{Re}(s) > 0} \left(|W_1(s)S(s)|^2 + |W_2(s)T(s)|^2 \right)^{\frac{1}{2}} \leq \gamma$$

for the smallest possible $\gamma > 0$, where $T(s) := 1 - S(s)$ and $W_2(s)$ represents the multiplicative uncertainty bound, with $|W_2(j\omega)| = |W(j\omega)|/|P(j\omega)|$, $\forall \omega \in \mathbb{R}$. The smallest achievable γ is the optimal performance level γ_{opt} , and the corresponding controller is denoted by C_{opt} . Typically, when P is infinite dimensional, so is the optimal controller.

Design Methods

Approximation of the Plant

One possible way to design a robust controller for an infinite-dimensional plant P is to design a robust controller C_a for an approximate finite-dimensional plant P_a ; (for a frequency domain approximation technique for infinite-dimensional systems, see Gu et al. (1989)). When W_1 , W_2 , and P_a are finite dimensional, standard state-space methods, Zhou et al. (1996), can be used to find a $\mathcal{H}_\infty$ controller C_a achieving

$$\left\| \begin{bmatrix} W_1 S_a \\ W_2 T_a \end{bmatrix} \right\|_\infty \leq \gamma_a$$

for the smallest possible γ_a , where $S_a := (1 + P_a C_a)^{-1}$ and $T_a = (1 - S_a)$. Then, the controller $C = C_a$ satisfies (a) and achieves the performance objective (d) with

$$\gamma = (\gamma_a + \varepsilon) \frac{1}{1 - \varepsilon}, \quad \varepsilon := \|C_a S_a (P - P_a)\|_\infty,$$

where it is assumed that the approximation of the plant is made in such a way that $\varepsilon < 1$. Clearly, if $\gamma_a \rightarrow \gamma_{\text{opt}}$ as $\varepsilon \rightarrow 0$, then $\gamma \rightarrow \gamma_{\text{opt}}$ as

$\varepsilon \rightarrow 0$. The conditions under which $\gamma_a \rightarrow \gamma_{\text{opt}}$ are discussed in Morris (2001).

Direct Design Methods

The classical two-Riccati equation approach, Zhou et al. (1996), developed for finite-dimensional systems, has been extended to various classes of infinite-dimensional systems by using the state-space techniques where semigroup theory plays an important role; see van Keulen (1993) for further details.

In order to illustrate some of the key steps of a frequency domain method developed in Foias et al. (1996), consider a specific example where the plant is given as

$$P(s) = \frac{(s-1)(s+2)e^{-hs}}{(s^2+2s+2)(s+1-3e^{-2hs})}, \quad h = \ln(2) \approx 0.693. \quad (1)$$

First, compute the location of the poles in $\mathbb{C}_+$ using available numerical tools for finding the roots of quasi-polynomials; see, e.g., Sipahi et al. (2011) for references. For the simple example chosen here, $P(s)$ has only one pole in $\mathbb{C}_+$, at $s = 0.5$ (for larger values of h , the number of unstable poles of P may be higher). Now, the plant can be factored as follows:

$$P(s) = \frac{M_N(s)N_O(s)}{M_D(s)} \quad (2)$$

where

$$M_N(s) = \frac{s-1}{s+1} e^{-hs} \quad M_D(s) = \frac{s-0.5}{s+0.5}$$

are all-pass (inner) transfer functions and

$$N_O(s) = \frac{(s+2)(s+1)}{(s^2+2s^2+2)(s+0.5)} \left(\frac{s-0.5}{s+1-3e^{-2hs}} \right)$$

is a minimum-phase (outer) transfer function. Note that

$$\frac{s - 0.5}{s + 1 - 3e^{-2hs}} = \frac{1}{1 + H_F(s)},$$

$$H_F(s) = 1.5 \frac{1 - e^{-2h(s-0.5)}}{s - 0.5}. \quad (3)$$

The impulse response of H_F is $h_F(t) = 1.5e^{t/2}$ when $t \in [0, 2h]$ and $h_F(t) = 0$ otherwise. Stability of N_O can also be verified from the Nyquist graph of H_F . Also, note that $N_O(s)$ can be factored as $N_O(s) = N_1(s)N_2(s)$ where

$$N_1(s) = \frac{(s+2)(s+1)}{(s^2+2s^2+2)} \left(\frac{1}{1+H_F(s)} \right),$$

$$N_2(s) = \frac{1}{s+0.5}$$

with $N_1, N_1^{-1} \in \mathcal{H}_\infty$, and N_2 is finite-dimensional (first order in this example).

The above steps illustrate *coprime factorizations* and *inner-outer factorizations* for systems with time delays (retarded case). For systems represented by PDEs or integrodifferential equations, plant transfer function can be factored similarly, provided that the poles and zeros in $\mathbb{C}_+$ can be computed numerically.

When the plant is in the form (2) given above and the weights W_1 and W_2 are rational, the optimal performance level and the corresponding optimal controller are obtained by the following procedure (see Foias et al. (1996) for details).

- *Controller parameterization* transforms the mixed sensitivity minimization to a problem of finding the smallest $\gamma > 0$ for which there exists $Q \in \mathcal{H}_\infty$ such that

$$\left\| \begin{bmatrix} W_1 \\ 0 \end{bmatrix} - \begin{bmatrix} W_1 N_2 \\ -W_2 N_2 \end{bmatrix} M_N(R + M_D Q) \right\|_\infty \leq \gamma$$

where $R(s)$ is a rational function (whose order is one less than the order of M_D) satisfying certain interpolation conditions at the zeros of $M_D(s)$.

- A *spectral factorization* determines $W_0 \in \mathcal{H}_\infty$ such that $W_0^{-1} \in \mathcal{H}_\infty$ and

$$\begin{aligned} & \left(|W_1(j\omega)|^2 + |W_2(j\omega)|^2 \right) |N_2(j\omega)|^2 \\ &= |W_0(j\omega)|^2 \quad \forall \omega \in \mathbb{R}, \end{aligned}$$

(here, it is assumed that $W_2 N_2$ and $(W_2 N_2)^{-1}$ are in $\mathcal{H}_\infty$).

- By using the norm-preserving property of the unitary matrices and the *commutant lifting theorem*, it has been shown that

$$\gamma_{\text{opt}} = \left\| \begin{bmatrix} \Gamma \\ \Upsilon \end{bmatrix} \right\|$$

where Γ is the *Hankel operator* whose symbol is

$$\begin{aligned} & M_D(-s) \left(M_N(-s) W_0^{-1}(-s) N_2(-s) \right. \\ & \left. W_1(-s) W_1(s) - W_0(s) R(s) \right) \end{aligned}$$

and Υ is the *Toeplitz operator* whose symbol is $W_1(s) W_2(s) N_2(s) W_0^{-1}(s)$. Moreover, under mild technical assumptions, the optimal controller is obtained from a nonzero $\psi_o \in \mathcal{H}_2$ satisfying

$$\left(\gamma_{\text{opt}}^2 - (\Gamma^* \Gamma + \Upsilon^* \Upsilon) \right) \psi_o = 0$$

The operator $(\Gamma^* \Gamma + \Upsilon^* \Upsilon)$ is in the form of a *skew-Toeplitz operator* that gives the name to this approach. See Foias et al. (1996) for a detailed exposition.

Optimal $\mathcal{H}_\infty$ -Controller

The above steps have been implemented, and the final optimal controller expression has been obtained in a simplified form described below.

Let $\alpha_1, \dots, \alpha_\ell \in \mathbb{C}_+$ be the zeros of $M_D(s)$, i.e., unstable poles of the plant (for simplicity of the exposition, they are assumed to be distinct). The sensitivity weight can be written as $W_1(s) = n W_1(s)/d W_1(s)$, for two coprime polynomials $n W_1$ and $d W_1$ with $\deg(n W_1) \leq \deg(d W_1) =: n_1 \geq 1$. Define

$$E_\gamma(s) := \left(\frac{W_1(-s) W_1(s)}{\gamma^2} - 1 \right)$$

and let $\beta_1, \dots, \beta_{2n_1}$ be the zeros of $E_\gamma(s)$, enumerated in such a way that $-\beta_{n_1+k} = \beta_k \in \overline{\mathbb{C}}_+$, for $k = 1, \dots, n_1$. For notational convenience, assume that the zeros of E_γ are distinct for $\gamma = \gamma_{\text{opt}}$.

Now define a rational function depending on $\gamma > 0$ and the weights W_1 and W_2 ,

$$F_\gamma(s) := \gamma \frac{dW_1(-s)}{nW_1(s)} G_\gamma(s)$$

where $G_\gamma \in \mathcal{H}_\infty$ is an outer function determined from the spectral factorization

$$G_\gamma(-s)G_\gamma(s) = \left(1 + \frac{W_2(-s)W_2(s)}{W_1(-s)W_1(s)} - \frac{W_2(-s)W_2(s)}{\gamma^2}\right)^{-1}.$$

With the above definitions, under certain mild conditions (satisfied generically in most practical cases), the optimal controller can be expressed as

$$C_{\text{opt}}(s) = \frac{E_\gamma(s)M_D(s)F_\gamma(s)L(s)}{1 + M_N(s)F_\gamma(s)L(s)} N_O^{-1}(s) \quad (4)$$

where $\gamma = \gamma_{\text{opt}}$ and $L(s) = L_2(s)/L_1(s)$ with polynomials L_1 and L_2 , of degree $n_1 + \ell - 1$, determined from the interpolation conditions:

$$L_1(\beta_k) + M_N(\beta_k)F_\gamma(\beta_k)L_2(\beta_k) = 0$$

$$k = 1, \dots, n_1$$

$$L_1(\alpha_k) + M_N(\alpha_k)F_\gamma(\alpha_k)L_2(\alpha_k) = 0$$

$$k = 1, \dots, \ell$$

$$L_2(-\beta_k) + M_N(\beta_k)F_\gamma(\beta_k)L_1(-\beta_k) = 0$$

$$k = 1, \dots, n_1$$

$$L_2(-\alpha_k) + M_N(\alpha_k)F_\gamma(\alpha_k)L_1(-\alpha_k) = 0$$

$$k = 1, \dots, \ell.$$

The above system of equations can be rewritten in the matrix form

$$\mathcal{R}_\gamma \Phi = 0 \quad (5)$$

where the $2(n_1 + \ell) \times 1$ vector Φ contains the coefficients of L_1 and L_2 and $\mathcal{R}_\gamma$ is a $2(n_1 + \ell) \times 2(n_1 + \ell)$ matrix which can be computed numerically when γ is fixed. The optimal performance level γ_{opt} is the largest γ which makes $\mathcal{R}_\gamma$ singular. The corresponding nonzero Φ gives $L(s)$, and hence, all the components of C_{opt} are computed.

Example 1 Consider the weighted sensitivity minimization for the plant (1) with the following first-order weights:

$$W_1(s) = \frac{1}{s}, \quad W_2(s) = k s \quad (6)$$

where $k > 0$ represents the relative importance of the multiplicative uncertainty with respect to the tracking performance under steplike reference inputs (see Doyle et al. 1992; Özbay 2000). With (6) the functions $E_\gamma(s)$ and $F_\gamma(s)$ are computed as

$$E_\gamma(s) = \frac{1 + \gamma^2 s^2}{-\gamma^2 s^2}, \quad F_\gamma(s) = \frac{-\gamma s}{ks^2 + k_\gamma s + 1},$$

$$\text{where } k_\gamma = \sqrt{2k - \frac{k^2}{\gamma^2}}. \quad (7)$$

In this example $\ell = 1$ and $n_1 = 1$, with $\alpha_1 = 0.5$, $\beta_1 = j/\gamma$. For $k = 0.1$, the largest γ which makes $\mathcal{R}_\gamma$ singular is $\gamma_{\text{opt}} = 7.452$, and the coefficients of the corresponding $L(s)$ are computed from the SVD of $\mathcal{R}_{\gamma_{\text{opt}}}$,

$$L(s) = \frac{-0.0867 - 0.99623 s}{-0.0867 + 0.99623 s} = \frac{0.087 + s}{0.087 - s}.$$

Note that zeros of $E_\gamma(s)M_D(s)$ in $\overline{\mathbb{C}}_+$ appear as roots of the equation

$$1 + M_N(s)F_\gamma(s)L(s) = 0.$$

Hence, there are *internal* unstable pole-zero cancelations in the representation (4). An internally stable implementation of this controller is shown in Gumussoy (2011) using a realization similar to (3).

The above approach can also be extended to a class of infinite-dimensional plants with infinitely many poles in $\mathbb{C}_+$; see Gumussoy and Özbay (2004) for technical details.

A recent book Özbay et al. (2018) includes many examples from distributed parameters and discusses internally stable realization of the optimal controller and its approximations.

Summary and Future Directions

This entry briefly summarized robust control problems involving linear time-invariant infinite-dimensional plants with dynamic uncertainty models. Salient features of these robust control problems are captured by the mixed sensitivity minimization problem, for which a numerical computational procedure is outlined under the assumption that the weights are rational functions. Note that different types of plant models involving probabilistic, parametric, or structured (MIMO case) uncertainty are left out in this entry. Other robust control problems that are not discussed here include simultaneous stabilization (control of finitely many plant models by a single robust controller) and strong stabilization (robust control with the added restriction that the controller must be stable) of infinite-dimensional systems. Stable robust controller design techniques for different types of systems with time delays are illustrated in Özbay (2010) and Wakaiki et al. (2013); see also their references.

For practical implementation of infinite-dimensional robust controllers, it is important to find low-order approximations of stable irrational transfer functions with prescribed $\mathcal{H}_\infty$ error bound. There exist many different approximation techniques for various types of transfer functions, but there is still need for computationally efficient algorithms in this area. Another interesting topic along the same lines is direct computation of fixed-order $\mathcal{H}_\infty$ controllers for infinite-dimensional plants. In fact, computation of $\mathcal{H}_\infty$ -optimal PID controllers is still a challenging problem for infinite-dimensional plants, except

for some time-delay systems satisfying certain simplifying structural assumptions. Advances in numerical optimization tools will play critical roles in the computation of low (or fixed)-order robust controller design for infinite-dimensional plants; see, e.g., Gumussoy and Michiels (2011) for recent results along this direction.

In the past, robust control of infinite-dimensional systems found applications in many different areas such as chemical processes, flexible structures, robotic systems, transportation systems, and aerospace. Robust control problems involving systems with time-varying and uncertain time delays appear in control of networks and control over networks. Ongoing research in the networked systems area include generalization of these problems to more complex and interconnected systems.

There are also many interesting robust control problems in biological systems, where typical underlying plant models are nonlinear and infinite dimensional. Some of these problems are solved under simplifying assumptions; it is expected that robust control theory will make significant contributions to this field by extensions of the existing results to more realistic plant and uncertainty models.

Robust Fault Diagnosis and Control

Steven X. Ding
University of Duisburg-Essen, Duisburg,
Germany

Abstract

Aiming at increasing system reliability and availability, integration of fault diagnosis into feedback control systems, and integrated design of control and diagnosis receive considerable attention in research and industrial applications. In the framework of robust control, integration of diagnosis and control systems can improve system robustness and fault tolerance. The core of such integrated systems is an observer that delivers needed information for a robust fault detection and feedback control.

Keywords

Observer-based fault diagnosis and control · Residual generation

Introduction

Advanced automatic control systems are marked by the high integration degree of digital electronics, intelligent sensors, and actuators. In parallel to this development, a new trend of integrating model-based fault detection and isolation (FDI) into the control systems can be observed (Patton et al. 2000; Blanke et al. 2006; Isermann 2006; Ding 2013), which is strongly driven by the increasing demands for system reliability and availability.

A critical issue surrounding the integration of a diagnostic module into a feedback control

loop is the interaction between the control and diagnosis. Initiated by Nett et al. (1988), study on the integrated design of control and diagnosis has received much attention, both in the research and application domains. The original idea of the integrated design scheme proposed in Nett et al. (1988) is to manage the interactions between the control and diagnosis in an integrated manner (Jacobson and Nett 1991; Ding 2009).

Robustness is an essential performance for model-based control and diagnostic systems. In the control and diagnosis framework, robustness is often addressed in different context (Ding 2013) and thus calls for special attention in the integrated design of control and diagnostic systems. In their study on fault-tolerant controller architecture, Zhou and Ren (2001) have proposed to deal with the integrated design in the framework of Youla parameterization of stabilization controllers (Zhou et al. 1996), which also builds the basis for achieving high robustness in an integrated control and diagnosis system. Below, we present the basic ideas and some representative schemes and methods for the integrated design of robust diagnosis and control systems.

Plant Model and Factorization Technique

Consider processes modeled by a linear time-invariant (LTI) system given in the state space representation

$$\begin{aligned}\dot{x}(t) &= Ax(t) + Bu(t) + E_d d(t) + E_f f(t) \\ y(t) &= Cx(t) + Du(t) + F_d d(t) + F_f f(t) \\ z(t) &= C_z x(t) + D_z u(t)\end{aligned}$$

where $x \in \mathcal{R}^n$, $y \in \mathcal{R}^m$, and $u \in \mathcal{R}^{k_u}$ stand for the system state, output, and input vectors, respectively. $z \in \mathcal{R}^{k_z}$ is the controlled output vector. $d \in \mathcal{R}^{k_d}$, $f \in \mathcal{R}^{k_f}$ denote disturbance and fault vectors, respectively. $A, B, C, D, C_z, D_z, E_d, E_f, F_d$, and F_f are known matrices of appropriate dimensions.

A transfer matrix $G(s) = D + C(sI - A)^{-1}B$ with the minimal state space realization (A, B, C, D) can be factorized into

$$\begin{aligned}G(s) &= \hat{M}^{-1}(s)\hat{N}(s) \\ \hat{M}(s) &= I - C(sI - A_L)^{-1}L \\ \hat{N}(s) &= D + C(sI - A_L)^{-1}B_L \\ A_L &= A - LC, B_L = B - LD\end{aligned}$$

where L is selected so that A_L is Hurwitz and can be interpreted as an observer gain matrix. This factorization is called left coprime (Zhou et al. 1996).

Parametrization of Stabilizing Controllers

Let

$$u(s) = K(s)y(s)$$

be an LTI feedback controller. By means of the well-known Youla parameterization (Zhou et al. 1996), all stabilizing controllers can be described and parametrized by

$$\begin{aligned}K(s) &= \hat{V}^{-1}(s)\hat{U}(s) \\ \hat{V}(s) &= \hat{X}(s) - Q_c(s)\hat{N}(s) \\ \hat{U}(s) &= \hat{Y}(s) - Q_c(s)\hat{M}(s) \\ \hat{X}(s) &= I - F(sI - A_L)^{-1}B_L \\ \hat{Y}(s) &= F(sI - A_L)^{-1}L\end{aligned}$$

where $Q_c(s)$ is a stable parameter matrix and F is selected so that $A_F = A + BF$ is Hurwitz and can be interpreted as a state feedback gain matrix.

Parametrizations of Residual Generators

Given the system under consideration, an LTI residual generator is a dynamic system with $u(t)$, $y(t)$ as its inputs and $r(t)$ as output which satisfies, for $d(t) = 0$, $f(t) = 0$,

$$\forall x(0), u(t), \lim_{t \rightarrow \infty} r(t) = 0.$$

Residual generation is the first step for a successful fault diagnosis. The generated residual vector is an indicator for the occurrence of a fault. It is well-known that all LTI residual generators can be parameterized by

$$r(s) = R(s) \left(\hat{M}(s)y(s) - \hat{N}(s)u(s) \right)$$

where $R(s)$ is a stable parameter matrix and called post-filter (Ding 2013).

Integration of Controller and Residual Generator into a Control Loop

It is remarkable that both the feedback controllers and residual generators can be parametrized based on the left coprime factorization of the plant model. This is the basis for an integration of diagnosis and control into a feedback control system. In Ding (2014), it is demonstrated that the abovementioned Youla parametrization form is in fact an observer-based feedback controller, which can be expressed by

$$u(s) = F\hat{x}(s) + Q_c(s) \left(\hat{N}(s)u(s) - \hat{M}(s)y(s) \right)$$

where $\hat{x}(s)$ is a state estimate delivered by a full-order state observer (Zhou et al. 1996; Anderson 1998). Moreover, the residual generator can also be written as

$$r(s) = R(s)r_o(s), r_o(s) = y(s) - \hat{y}(s)$$

with $\hat{y}(s)$ being the output estimate delivered by an observer (Ding 2013). As a result, a stabilization feedback controller and residual generator can be integrated into a dynamic system of the following form

$$\dot{\hat{x}}(t) = A\hat{x}(t) + Bu(t) + Lr_o(t)$$

$$= A_L\hat{x}(t) + B_Lu(t) + Ly(t)$$

$$r_o(t) = y(t) - \hat{y}(t), \hat{y}(t) = C\hat{x}(t) + Du(t)$$

$$\begin{bmatrix} u(s) \\ r(s) \end{bmatrix} = \begin{bmatrix} F\hat{x}(s) \\ 0 \end{bmatrix} + \begin{bmatrix} -Q_c(s) \\ R(s) \end{bmatrix} r_o(s).$$

The core of the above control and diagnostic system is a state observer that delivers a state estimation $\hat{x}(t)$ and the primary residual vector $r_o(t)$. The design parameters of this integrated control and diagnosis system are L , F , the observer and state feedback control gain matrices, as well as $Q_c(s)$, $R(s)$.

Robustness of Diagnostic and Control Systems

While in the robust control framework the controller design is typically formulated as minimizing a system norm of the transfer function matrix from the disturbance vector d to the control output z (Zhou et al. 1996), the design objective of a robust fault detection system consists in an optimal trade-off between the robustness against d and the sensitivity to the fault vector f . Considering that

$$\begin{aligned} r(s) &= R(s) (y(s) - \hat{y}(s)) \\ &= R(s) \left(\hat{N}_d(s)d(s) + \hat{N}_f(s)f(s) \right) \end{aligned}$$

$$\hat{N}_d(s) = F_d + C(sI - A_L)^{-1}(E_d - LF_d)$$

$$\hat{N}_f(s) = F_f + C(sI - A_L)^{-1}(E_f - LF_f)$$

(Ding 2013), the design objective can be formulated as

$$\sup_{R(s)} \frac{\|R(s)\hat{N}_f(s)\|_{index}}{\|R(s)\hat{N}_d(s)\|}$$

or in a suboptimum form as finding $R(s)$ so that for some given $\alpha > 0$, $\beta > 0$

$$\|R(s)\hat{N}_d(s)\| \leq \alpha, \|R(s)\hat{N}_f(s)\|_{index} > \beta.$$

Similar to the robust controller design, a (system) norm like $\mathcal{H}_2$ or $\mathcal{H}_\infty$ norm, denoted by $\|\cdot\|$, is applied for the evaluation of the influence of the disturbances. Differently, the evaluation of the sensitivity to the fault vector, expressed by $R(s)\hat{N}_f(s)$, can be realized either using a system norm or the so-called $\mathcal{H}_-$ index, denoted by $\|\cdot\|_-$, which indicates the minimum influence of f on r (Ding 2013).

In order to detect the fault occurrence reliably and successfully, a decision-making procedure is needed. It consists of a further evaluation of the residual signal and a detection logic. Typically, a signal norm of r , e.g., $\mathcal{L}_2$ norm, and a simple detection logic like

$$\begin{cases} \|r\| > J_{th} \implies \text{Alarm for fault} \\ \|r\| \leq J_{th} \implies \text{Fault-free} \end{cases}$$

are adopted for this purpose, where J_{th} is a further design parameter and called threshold (Ding 2013). The threshold setting depends on the dynamics of r , its norm-based evaluation, and has significant influence on the fault detection performance. For the purpose of reducing false alarms, the threshold is often set as

$$\begin{aligned} J_{th} &= \sup_{f=0, \|d\| \leq d_d} \|r\| \\ &= \sup_{f=0, \|d\| \leq d_d} \|R(s)\hat{N}_d(s)d(s)\|. \end{aligned}$$

That is, the threshold is set to be the maximum value of the influence of the disturbances on the residual signal in the fault-free case. Thus, different designs of the residual generator will result in different threshold settings. In this context, an optimal design of a fault diagnosis system is understood as an integrated design of the residual generator, the evaluation function, and the threshold (Ding 2013).

An Integrated Design Scheme for Robust Diagnosis and Control

Assume that the system under consideration satisfies the following conditions:

- $\|d\|_2 \leq \delta_d$
- (A, B) is stabilizable and (C, A) is detectable
- $D = 0$
- $D_z^T D_z > 0$ and $F_d F_d^T > 0$
- $\begin{bmatrix} A - j\omega I & B \\ C_z & D \end{bmatrix}$ has full column rank for all ω
- $\begin{bmatrix} A - j\omega I & E_d \\ C & F_d \end{bmatrix}$ has full row rank for all ω .

Then, the following observer and state feedback gain matrices

$$\begin{aligned} L^* &= (E_d F_d^T + Y C^T) (F_d F_d^T)^{-1} \\ F^* &= - (D_z^T D_z)^{-1} (B^T X + D_z^T C_z) \end{aligned}$$

as well as

$$Q_c^*(s) = 0, R^*(s) = (F_d F_d^T)^{-1/2}$$

result in an optimal integrated design of the robust diagnostic and control system with:

- $\mathcal{H}_2$ optimal control performance and
- maximal fault detectability and the optimal threshold setting

$$J_{th} = \sup_{f=0, \|d\| \leq \delta_d} \|r\|_2 = \delta_d$$

where $Y \geq 0, X \geq 0$ are, respectively, the solution of the following two Riccati equations

$$\begin{aligned} AY + Y A^T + E_d E_d^T - (E_d F_d^T + Y C^T) \cdot \\ (F_d F_d^T)^{-1} (E_d F_d^T + Y C^T)^T &= 0 \\ A^T X + X A + C_z^T C_z - (C_z^T D_z + X B) \cdot \\ (D_z^T D_z)^{-1} (C_z^T D_z + X B)^T &= 0. \end{aligned}$$

That L^*, F^* lead to minimizing the $\mathcal{H}_2$ norm of the transfer matrix from d to z is a well-known result (Zhou et al. 1996). The optimal fault detection performance can be understood from two different viewpoints:

- optimum in the sense of

$$\forall \omega, \sup_{R(s)} \frac{\sigma_i \left(R(j\omega) \hat{N}_f(j\omega) \right)}{\left\| R(s) \hat{N}_d(s) \right\|_{\infty}} \\ = \sigma_i \left(\left(F_d F_d^T \right)^{-1/2} \hat{N}_f^*(j\omega) \right)$$

where $\sigma_i \left(R(j\omega) \hat{N}_f(j\omega) \right)$ is the i -th singular value of matrix $R(j\omega) \hat{N}_f(j\omega)$, $i = 1, \dots, k_f$, $\hat{N}_f^*(s) = \hat{N}_f(s) |_{L=L^*}$ (Ding 2013)

- a fault that can be detected by any LTI detection system will also be detected using the detection system with the above parameter and threshold setting. Thus, this detection system provides the maximal fault detectability (Ding 2013).

It is worth to remark that:

- the assumptions mentioned above are standard in the $\mathcal{H}_2$ optimal control (Zhou et al. 1996)
- the optimization problem

$$\forall \omega, \sup_{R(s)} \frac{\sigma_i \left(R(j\omega) \hat{N}_f(j\omega) \right)}{\left\| R(s) \hat{N}_d(s) \right\|_{\infty}}$$

is a more general form of the so-called $\mathcal{H}_-/\mathcal{H}_{\infty}$ or $\mathcal{H}_{\infty}/\mathcal{H}_{\infty}$ optimization of observer-based fault detection systems, and thus its solution is called unified solution (Ding 2013)

- The solution given above is a state space realization of the robust fault detection problems, which is, e.g., described in Ding (2013)
- this integrated design scheme can also be applied to discrete-time and stochastic systems (Ding 2013).

Summary and Future Directions

Increasing reliability and availability of advanced automatic control systems is of considerable

practical interests. Integration of fault diagnosis into feedback control systems and integrated design of robust control and diagnosis are useful solutions for real time applications. They can also be integrated into a fault-tolerant control system (Blanke et al. 2006; Zhou and Ren 2001). A further potential application field is fault diagnosis in feedback control loops using embedded residual signals.

From the viewpoint of research, integrated design of robust control and diagnosis in nonlinear and time-varying dynamic systems with parameter faults are challenging issues. The $\mathcal{L}_2$ -gain technique for nonlinear control (Van der Schaft 2000) and diagnosis (Yang et al. 2016) and the fault detection schemes proposed in Li and Zhou (2009) and Zhong et al. (2016) are promising results for the future investigations in this area.

Robust H_2 Performance in Feedback Control

Fernando Paganini
Universidad ORT Uruguay, Montevideo,
Uruguay

Abstract

This entry discusses an important compromise in feedback design: reconciling the superior performance characteristics of the $\mathcal{H}_2$ optimization criterion, with robustness requirements expressed through induced norms such as $\mathcal{H}_\infty$. The fact that both criteria have frequency-domain characterizations and involve similar state-space machinery motivated many researchers to seek an adequate combination. We review here robust $\mathcal{H}_2$ analysis methods based on convex optimization developed in the 1990s and comment on their implications for controller synthesis.

Keywords

Linear matrix inequalities · Mixed $\mathcal{H}_2/\mathcal{H}_\infty$ control · Robustness analysis · Structured uncertainty

Introduction

Can mathematics help us deal with the inevitable theory-practice gap? Should we be optimistic and assume that discrepancies between models and nature are random and neutral towards our actions or be pessimistic and design for the worst such discrepancies? Feedback control theory has struggled with these questions, perhaps more so than other fields.

During the surge of optimal control in the 1960s, optimism carried the day. A prominent example is the LQG ($\mathcal{H}_2$) regulator, which minimizes the effect of random disturbances and has an elegant state-space solution; in comparison, the frequency-domain designs of classical control appeared primitive and conservative. But the pessimists struck back in the late 1970s, showing things could go very wrong (unstable) with LQG, when a parameter variation was introduced in the plant model. This ushered in the robust control era of the 1980s, with its worst-case analysis of stability over deterministic sets of plants, leading to other design metrics such as $\mathcal{H}_\infty$ control. In this mentality, exogenous disturbances were also treated as an adversary to be protected against in the worst case, perhaps an excess of pessimism.

The robust $\mathcal{H}_2$ problem incarnates the search for a middle ground, where stability is treated with the conservatism it deserves, but performance is optimized for a more neutral noise. This entry summarizes efforts made around the 1990s to seek this compromise.

$\mathcal{H}_2$ Optimal Control

In the feedback diagram of Fig. 1, signals are vector valued, and we focus on continuous time. G is a linear system with a given state-space representation. Initially omit the upper loop (set $\Delta = 0$). The LQG regulator is the controller K that internally stabilizes the feedback loop and minimizes the variance of the error variable z , assuming the input v is white Gaussian noise.

For an alternative description, denote by $\hat{T}_{zv}(s)$ the closed-loop transfer function from v to z ; we wish to design K such that $\hat{T}_{zv}(s)$ is

Robust H_2 Performance in Feedback Control, Fig. 1 Feedback control and model uncertainty

analytic in $\text{Re}(s) \geq 0$ and has minimum $\mathcal{H}_2$ norm, defined by

$$\|\hat{T}_{zv}\|_{\mathcal{H}_2} = \left(\int_{-\infty}^{\infty} \text{Tr}(\hat{T}_{zv}(j\omega)^* \hat{T}_{zv}(j\omega)) \frac{d\omega}{2\pi} \right)^{\frac{1}{2}}; \quad (1)$$

here Tr denotes matrix trace and $*$ denotes conjugate transpose. The equivalence between this $\mathcal{H}_2$ -optimal control and LQG follows from classical filtering, modeling v as uncorrelated components of unit power spectral density over all frequency. By adding a filter in the input of G , noise of known, colored spectrum can be accommodated as well.

A different motivation, in the case of scalar v , is to observe that $\|\hat{T}_{zv}\|_{\mathcal{H}_2}^2$ is the energy ($\mathcal{L}_2$ -norm square) of the system impulse response. Thus it measures the transient error in response to known inputs or initial conditions which may be generated by an impulse.

The $\mathcal{H}_2$ (LQG) optimal feedback has an elegant solution, computable in state-space through two algebraic Riccati equations (AREs). Its quick popularity was, however, hampered due to its lack of *stability margins*: a small error in model parameters can make the closed-loop unstable (Doyle 1978). This motivated methods to explicitly address such modeling errors.

Model Uncertainty and Robustness

Suppose some parameter in the model of G is uncertain, $\alpha = \alpha_0 + \kappa\delta$, $\delta \in [-1, 1]$; often,

Robust H_2 Performance in Feedback Control, Fig. 2 Robustness analysis setup

the normalized variation δ can be “pulled out” into the *uncertainty block* Δ of Fig. 1. The same technique can account for unmodeled linear time-invariant (LTI) dynamics, e.g., high frequency effects: they can be “covered” by a normalized transfer function $\hat{\Delta}(j\omega)$ and frequency weights that connect it to G . Even further, a nonlinear or time-varying (NL,TV) modeling error can be represented through an *operator* Δ in signal space. The references contain details on this modeling technique.

To analyze the effect of such errors, suppose K has been chosen to stabilize G and M is the resulting closed-loop system, with state-space representation

$$\begin{aligned} \dot{x} &= Ax + B_p p + B_v v, \\ q &= C_q x, \\ z &= C_z x. \end{aligned} \quad (2)$$

A is an $n \times n$ stable (Hurwitz) matrix, and for simplicity there are no feed-through terms. Figure 2, represents the interconnection of M with the uncertainty.

To quantify the size of uncertainty, it is convenient to use an *induced norm* (gain) in signal space and constrain Δ to the normalized ball $\{\|\Delta\| \leq 1\}$. If the subsystem M_{qp} in feedback with Δ satisfies itself the induced norm constraint $\|M_{qp}\| < 1$, the small gain theorem implies *robust stability* over the entire ball. Focusing for the rest of this article on the $\mathcal{L}_2$ signal space (square-integrable functions), the latter induced norm is equivalent to the $\mathcal{H}_\infty$ norm of the transfer function:

$$\|\hat{M}_{qp}(s)\|_{\mathcal{H}_\infty} := \operatorname{ess\,sup}_{\omega \in \mathbb{R}} \bar{\sigma}(\hat{M}_{qp}(j\omega)),$$

where $\bar{\sigma}(\cdot)$ denotes matrix maximum singular value.

This motivates $\mathcal{H}_\infty$ -optimal control: design K to minimize the above quantity with internal stability. This problem also admits state-space solutions based on AREs and thus is a valid competing paradigm to $\mathcal{H}_2$.

To accommodate multiple sources of uncertainty within Fig. 1, we can use a *block diagonal* structure:

$$\Delta = \operatorname{diag}[\Delta_1, \dots, \Delta_d]. \quad (3)$$

Here, different uncertainty blocks (parametric, LTI, LTV, or NL) enter in separate “channels”; $\mathbf{B}_\Delta$ denotes the unit ball of operators with the prescribed structure. For stability studies, *causality* of the operator is required.

Robust stability under structured uncertainty is a rich topic: we refer to the article on the *structured singular value* (μ) in this encyclopedia. We invoke here robustness conditions based on the set $\mathbf{A}$ of positive definite matrix *scalings* or *multipliers* of the form:

$$\Lambda = \operatorname{diag}[\lambda_1 I, \dots, \lambda_d I], \quad (4)$$

with submatrices of the same dimensions as the blocks in (3), thus commuting with a matrix Δ of that structure.

Consider the frequency family of matrix inequalities

$$\begin{aligned} \hat{M}_{qp}^*(j\omega)\Lambda(\omega)\hat{M}_{qp}(j\omega) - \Lambda(\omega) &< 0 \quad \forall \omega; \\ \Lambda(\omega) &\in \mathbf{A}. \end{aligned} \quad (5)$$

At each ω , this is a linear matrix inequality (LMI); testing its feasibility is a convex, tractable problem. A solution implies the *scaled-small gain condition*

$$\bar{\sigma}\left(\Lambda(\omega)^{\frac{1}{2}}\hat{M}_{qp}(j\omega)\Lambda^{-\frac{1}{2}}(\omega)\right) < 1;$$

this “ μ upper bound” implies robust stabil-

ity when uncertainty is LTI, through commuting $\Lambda(\omega)$ with $\hat{\Delta}(j\omega)$.

If uncertainty is NLTV, (5) must be strengthened to enforce $\Lambda(\omega) \equiv \Lambda$, constant in frequency. This condition turns out to be both necessary and sufficient for robust stability. Here the LMIs would be coupled in frequency; however, the Kalman-Yakubovich-Popov lemma reduces them to an equivalent LMI in terms of the state-space matrices in (2), with variables $\Lambda \in \mathbf{A}$ and an $n \times n$ matrix $P > 0$:

$$\begin{bmatrix} A^*P + PA + C_q^*\Lambda C_q & PB_p \\ B_p^*P & -\Lambda \end{bmatrix} < 0. \quad (6)$$

What about performance? The mapping $T_{zv}(\Delta)$ between the disturbance v and the error z now depends on the uncertainty. The default procedure in robust control has been to measure performance with the same induced norm, evaluating $\|T_{zv}(\Delta)\|_{\mathcal{L}_2 \rightarrow \mathcal{L}_2}$ in the worst-case over $\Delta \in \mathbf{B}_\Delta$. This can be computed with similar complexity to establishing robust stability. It amounts, however, to treating noise with the same worst-case mentality as stability, a questionable choice. For instance, in LTI systems the worst-case signals are sinusoids at the worst frequency and spatial direction; while one should protect against such signals arising in the Δ -loop due to instability, it is not natural to expect them as external disturbances, which are usually of broad spectrum.

Robust $\mathcal{H}_2$ Performance Analysis

In the absence of uncertainty, the $\mathcal{H}_2$ norm of the nominal mapping $T_{zv}(0) = M_{zv}$ provides a natural performance criterion, measuring the response to flat-spectrum disturbances or the transient response. When uncertainty is present, it motivates a worst-case analysis of stability; a natural combination is to impose *robust $\mathcal{H}_2$ performance*: evaluating the worst-case $\mathcal{H}_2$ norm of $T_{zv}(\Delta)$ over the uncertainty class $\mathbf{B}_\Delta$. We will highlight some methods based on semidefinite programming to perform such evaluations; for further details and comparisons, we refer to Paganini and Feron (1999).

A Frequency Domain Robust Performance Criterion

Consider the following optimization:

$$J_f := \inf \int_{-\infty}^{\infty} \text{Tr}(Y(\omega)) \frac{d\omega}{2\pi}, \text{ subject to}$$

$$\hat{M}(j\omega)^* \begin{bmatrix} \Lambda(\omega) & 0 \\ 0 & I \end{bmatrix} \hat{M}(j\omega) - \begin{bmatrix} \Lambda(\omega) & 0 \\ 0 & Y(\omega) \end{bmatrix} < 0 \quad (7)$$

for each ω , and $\Lambda(\omega) \in \mathbf{\Lambda}$.

Here $\hat{M}$ is the transfer function in Fig. 2; a submatrix of the above includes (5), implying robust stability under structured LTI uncertainty. Furthermore, we have the robust $\mathcal{H}_2$ performance bound (Paganini 1999):

$$\sup_{\Delta \in \mathbf{B}_{\mathbf{\Lambda}}^{LTI}} \|T_{zv}(\Delta)\|_{\mathcal{H}_2}^2 \leq J_f. \quad (8)$$

We sketch the argument based on the Fourier transforms $\hat{p}(j\omega)$, etc., for signals in Fig. 2. Applying the quadratic form in (7) to the joint vector of $\hat{p}$ and $\hat{v}$ gives

$$\sum_{i=1}^d \lambda_i(\omega) |\hat{q}_i|^2 + |\hat{z}|^2 \leq \sum_{i=1}^d \lambda_i(\omega) |\hat{p}_i|^2 + \hat{v}^* Y(\omega) \hat{v}.$$

The subvectors $\hat{p}_i$, $\hat{q}_i$ correspond to uncertainty blocks, $\hat{p}_i = \hat{\Delta}_i(j\omega) \hat{q}_i$; since $\bar{\sigma}(\hat{\Delta}_i(j\omega)) \leq 1$, $|\hat{q}_i| \geq |\hat{p}_i|$. Also $\lambda_i(\omega) > 0$, so these terms can be simplified, leading to

$$|\hat{T}_{zv}(j\omega) \hat{v}|^2 = |\hat{z}|^2 \leq \hat{v}^* Y(\omega) \hat{v}.$$

This means $\hat{T}_{zv}(j\omega)^* \hat{T}_{zv}(j\omega) \leq Y(\omega)$ for every Δ , and therefore the $\mathcal{H}_2$ norm bound

$$\|T_{zv}(\Delta)\|_{\mathcal{H}_2}^2 \leq \int_{-\infty}^{\infty} \text{Tr}(Y(\omega)) \frac{d\omega}{2\pi}$$

holds, from which (8) follows.

The computation involved in (7) at each frequency is a semidefinite program (SDP): minimizing the linear cost $\text{Tr}(Y(\omega))$ subject to an LMI constraint, a tractable problem. Adding a frequency sweep, we have a practical method to bound the desired robust performance.

The inequality (8) is in general strict. Beyond the usual conservatism of convex bounds for μ , when noise is of dimension m , a conservatism of up to this order may appear; an improvement to address this issue with augmented SDPs is given in Sznaier et al. (2002). Finally, causality of the uncertainty is not imposed in the frequency-domain criterion.

As in the study of robust stability, we wish to extend the analysis to NLTV uncertainty blocks. Now the mapping $T_{zv}(\Delta)$ can no longer be represented by a transfer function, so what is the “ $\mathcal{H}_2$ ” cost? We return to our motivation for this performance notion: to measure the effect of disturbances of flat spectrum.

In Paganini (1999), the flat-spectrum property is imposed as a deterministic constraint on the input disturbances. For the scalar v case, define $W_{\eta,B} \subset \mathcal{L}_2$ by the family of *integral quadratic constraints*:

$$\int_{-\beta}^{\beta} |v(j\omega)|^2 \frac{d\omega}{2\pi} \begin{cases} \leq \frac{\beta}{\pi} + \eta & \forall \beta; \\ \geq \frac{\beta}{\pi} - \eta, & \beta \in [0, B]. \end{cases} \quad (9)$$

This imposes that the cumulative spectrum is approximately linear (to a tolerance $\eta > 0$), up to bandwidth B , and has sublinear growth beyond that. Extensions to vector-valued signals are also given. For a stable LTI system T_{zv} , it is not difficult to verify that

$$\|T_{zv}\|_{\mathcal{H}_2}^2 = \lim_{\substack{\eta \rightarrow 0 \\ B \rightarrow \infty}} \sup_{v \in W_{\eta,B}} \|T_{zv} v\|_2^2,$$

but the right-hand side applies to NLTV systems as well. The following result can be established in the latter case:

$$\lim_{\substack{\eta \rightarrow 0 \\ B \rightarrow \infty}} \sup_{v \in W_{\eta,B}, \Delta \in \mathbf{B}_{\mathbf{\Lambda}}^{NLTV}} \|T_{zv}(\Delta) v\|_2^2 = J'_f,$$

where the right-hand side is the variant of (7) with the restriction that $\Lambda(\omega) \equiv \mathbf{\Lambda}$, constant in frequency. In this case the characterization is *exact*, with equality above. This follows from a duality argument in function space, where $Y(\omega)$ appears as the multiplier for the constraint in (9). While coupled in frequency, J'_f is again equivalent to a finite-dimensional SDP in state space.

Let us review, instead, a different state-space method, motivated by alternate definitions of the $\mathcal{H}_2$ cost.

A State-Space Criterion Invoking Causality

Consider the semidefinite program

$$J_s := \inf \operatorname{Tr}(B_v^* P B_v) \text{ subject to } P > 0, \Lambda \in \mathbf{A},$$

$$\begin{bmatrix} A^* P + P A + C_q^* \Lambda C_q + C_z^* C_z & P B_p \\ B_p^* P & -\Lambda \end{bmatrix} < 0. \quad (10)$$

The LMI above is very similar to (6); indeed it provides a robust stability certificate and in addition a bound on a generalized $\mathcal{H}_2$ cost, for arbitrary (NLTV) causal uncertainty blocks. Again, we sketch the argument.

For stability, consider the system of Fig. 2 with $v \equiv 0$, initial condition $x(0) = x_0$. Define the storage function $V(x) = x^* P x$; differentiating it under (2) and applying the LMI (10) to the joint vector of $x(t)$, $p(t)$ yield

$$\dot{V} + |z|^2 \leq -q^* \Lambda q + p^* \Lambda p = \sum_{i=1}^d \lambda_i (|p_i|^2 - |q_i|^2).$$

Integrating the above over $(0, t)$, the sum on the right becomes nonpositive because $\lambda_i > 0$ and the operator $\Delta_i : q_i \rightarrow p_i$ is causal and contractive. This leads to

$$V(x(t)) + \int_0^t |z(\tau)|^2 d\tau \leq V(x_0), \quad (11)$$

which implies Lyapunov stability; the bound can be sharpened to prove asymptotic stability. Also, letting $t \rightarrow \infty$ yields the energy bound $\|z\|_2^2 \leq V(x_0)$.

Suppose now that x_0 is generated by applying to the (causal) system at rest, an impulse $v(t) = \delta(t)$, assumed scalar. The result is $x(0+) = B_v$, so $V(x_0) = B_v^* P B_v$; the impulse response energy of $T_{zv}(\Delta)$ is thus bounded. Minimizing over P, Λ leads to the robust $\mathcal{H}_2$ performance bound

$$\sup_{\Delta \in \mathbf{B}_{\Delta}^{NLTV}} \|T_{zv}(\Delta) \delta(t)\|_2^2 \leq J_s,$$

where the $\mathcal{H}_2$ cost is generalized as the impulse response energy. An extension to multiple impulse channels is available. This kind of result was first obtained by Stoorvogel (1993) for unstructured uncertainty.

An alternate notion of $\mathcal{H}_2$ cost for NLTV systems, also considered in Stoorvogel (1993), is the average output variance when the input is random white noise. This is formalized by replacing (2) with a stochastic differential equation (e.g., Oksendal 1985) and extending the bound (11) using Ito calculus; for details see Paganini and Feron (1999). The following robust $\mathcal{H}_2$ performance bound is obtained:

$$\limsup_{\tau \rightarrow \infty} \frac{1}{\tau} \int_0^{\tau} E|z(t)|^2 dt \leq J_s \quad \forall \Delta \in \mathbf{B}_{\Delta}^{NLTV}.$$

What if the uncertainty is time invariant? Incorporating frequency-dependent scalings, with causality, into the state-space approach must be done approximately, generating $\hat{\Lambda}(j\omega)$ through the span of a predefined finite basis of causal, rational transfer functions. Searching over this basis for a bound on the impulse response energy can be pursued with state-space SDPs, now of a size increasing with the basis dimensionality. We refer to Feron (1997) for details.

Robust $\mathcal{H}_2$ Synthesis

Prior sections have focused on the robustness *analysis* of a closed-loop system M , obtained from G after designing a nominally stabilizing controller. Can we *synthesize* K with robust $\mathcal{H}_2$ performance as an objective? We overview some contributions to this question.

Multiojective $\mathcal{H}_2/\mathcal{H}_{\infty}$ Control

Let us discuss first the more modest objective of optimizing *nominal* $\mathcal{H}_2$ performance while guaranteeing robust stability. If the uncertainty block Δ in Fig. 2 is unstructured, the problem is equivalent to

$$\text{Minimize } \|\hat{M}_{zv}\|_{\mathcal{H}_2}, \text{ subject to } \|\hat{M}_{qp}\|_{\mathcal{H}_{\infty}} < 1.$$

Using a Youla parameterization of stabilizing controllers, $\hat{M}(s)$ depends affinely on a stable parameter $\hat{Q}(s)$; this makes the optimization over $\hat{Q}$ convex. However it has been shown to give infinite-dimensional solutions that must be approximated by suitable truncations; see Sznaier et al. (2000) and references therein.

To better exploit the state-space structure common to $\mathcal{H}_2$ and $\mathcal{H}_\infty$ synthesis, Bernstein and Haddad (1989) proposed a simplification: minimize an *auxiliary cost* that upper bounds the $\mathcal{H}_2$ norm while imposing the $\mathcal{H}_\infty$ constraint, through a common storage function. This cost is optimized by controllers of the order of the plant, characterized in terms of coupled AREs; later on Khargonekar and Rotea (1991) recast this problem using convex optimization. Also Zhou et al. (1994) and Doyle et al. (1994) studied the dual (transpose) structure.

The latter version is in fact directly related to the analysis condition (10), with a fixed $\Lambda = \lambda I$. A matrix P satisfying this condition imposes the $\mathcal{H}_\infty$ norm restriction and upper bounds the nominal $\mathcal{H}_2$ cost. This idea of imposing multiple objectives through a common storage function has more general applicability: Scherer et al. (1997) showed that all such problems admit tractable synthesis based on LMIs, with solutions of the same order as the plant.

Synthesis for Robust Performance

We have seen that rather than just an upper bound on nominal performance, (10) ensures the more stringent robust $\mathcal{H}_2$ performance requirement; therefore it becomes the basis of a robust $\mathcal{H}_2$ synthesis technique. In Stoorvogel (1993) this method is laid out for unstructured uncertainty: search linearly over the scalar λ and solve the auxiliary cost synthesis problem for each λ .

What about structured uncertainty? We run here into a general difficulty of such synthesis questions, even for robust stability alone. In that case, seeking simultaneously a controller K and a scaling Λ so that conditions (5) or (6) are satisfied by the resulting M is not a computationally friendly problem. In the absence of a general solution method, iterating between an $\mathcal{H}_\infty$ design of K for fixed Λ and the analysis

conditions to find Λ is commonly used for design.

Things can be no easier for robust $\mathcal{H}_2$ performance, but the iterative procedure does generalize to the conditions in (10): for fixed K , the SDP will return structured Λ 's, which can then be fixed for a multiobjective synthesis step based on the “auxiliary cost” in (10) as discussed above. If constant Λ are used (designing for NLTV uncertainty), all controllers obtained are of the order of the plant.

If uncertainty is LTI, an alternative is to carry out the analysis step in the frequency domain, finding a $\Lambda(\omega)$, $Y(\omega)$ through (7). In the corresponding situation for μ -synthesis, where only $\Lambda(\omega)$ is found, a step of fitting and spectral factorization is needed to approximate such scalings through a rational weights, which are then incorporated into $\mathcal{H}_\infty$ synthesis. A similar frequency weight in the performance channel can approximate the effect of $Y(\omega)$, thus relying on weighted $\mathcal{H}_\infty$ synthesis to pursue the $\mathcal{H}_2$ performance objective. Of course, the order of the resulting controllers is increased.

Summary and Future Directions

The tradeoff between performance and robustness is essential to feedback control. In the case of linear multivariable design, it motivated a compromise between $\mathcal{H}_2$ performance and $\mathcal{H}_\infty$ -type robustness, pursued with the state-space and frequency-domain tools common to these metrics. We have highlighted robust $\mathcal{H}_2$ analysis conditions obtained in the 1990s based on semidefinite programming, which provided the greatest flexibility to integrate the aforementioned tools and different points of view (worst-case, average case) present in this problem. As in other situations, the robust synthesis question has proven more difficult: design cannot be “automated” to the degree that was once envisioned.

The passage of time makes issues that once attracted strong attention look narrow in scope, so it is not natural to indicate directions that directly follow on this work. Perhaps the best

legacy that the robust $\mathcal{H}_2$ generation can take to other problems is the willingness to integrate various disciplines (dynamics, operator theory, stochastics, optimization) to face the demands of applied mathematical research.

Robust Model Predictive Control

R

Saša V. Raković

School of Automation, Beijing Institute of Technology, Beijing, China

Abstract

Model predictive control (MPC) is indisputably one of the rare modern control techniques that has significantly affected control engineering practice due to its natural ability to systematically handle constraints and optimize performance. Robust MPC is an improved form of MPC that is intrinsically

robust in the face of uncertainty. The main goal of robust MPC is to devise an optimization-based control synthesis method that accounts for the intricate interactions of the uncertainty with the system, constraints, and performance criteria in a theoretically rigorous and computationally tractable way.

Model predictive control · Robust model predictive control · Robust optimal control · Robust stability

Introduction

Robust MPC synthesis (Raković 1233) is best seen as a repetitive decision-making process, in which the underlying decision-making process is a robust optimal control (ROC) problem. The ROC problem is formulated in such a way so as to guarantee that all possible predictions of the controlled state and control actions sequences satisfy constraints and that the “worst-case” cost is minimized. The decision variable in the underlying ROC problem is a control policy, which is a sequence of control laws and which enables different control actions at different predicted states. Robust MPC makes use of the solution to the associated ROC problem in a recursive manner in order to implement the feedback control law, which is, in fact, equal to the first control law of an optimal control policy. A theoretically exact robust MPC can be obtained either by employing, in a repetitive fashion, the dynamic programming solution of the ROC problem or by solving online, in a recursive manner, corresponding infinite-dimensional minimaximization. The associated computational complexity has considerably hampered practical applicability of exact robust MPC, and it has made robust MPC an active research field with the prime challenge to devise design methods that adequately handle the effects of the uncertainty and yet are computationally plausible.

Recent research in MPC has witnessed advances across areas of robust, stochastic, and adaptive MPC. Research in these areas

has led to a plethora of MPC algorithms that address specific forms of uncertainty affecting the system under consideration. It is somewhat an unfortunate fact that a number of recent proposals blur the boundaries between robust, stochastic, and adaptive MPC syntheses, which strictly speaking belong to distinctly different mathematical classes. Failing to recognize inevitable heterogeneity of MPC under uncertainty syntheses exhibits potential misunderstanding of appropriate approach to handling different types of uncertainty. The information available about the uncertainty dictates directly the theoretically correct class of MPC under uncertainty.

Understanding MPC Under Uncertainty

The uncertainty types underpinning robust, stochastic, and adaptive MPC are illustrated by a scalar discrete time system

$$x^+ = x + u + w \text{ with } w \in \mathbb{W} := \{-1, 0, 1\},$$

where x is the state, u is the control, w is the uncertainty, and x^+ is the successor state.

Robust MPC is concerned with the set-membership uncertainty, for which the underlying available information on the uncertainty is that at any time instance $w_k \in \mathbb{W} = \{-1, 0, 1\}$. When at any time instance only state x_k is known, state feedback control laws $u_k(\cdot)$ with values $u_k(x_k)$ are structurally permissible, and this information pattern leads to a *minimax* MPC problem. Likewise, when at any time instance both state x_k and uncertainty w_k are known, state-uncertainty feedback control laws $u_k(\cdot, \cdot)$ with values $u_k(x_k, w_k)$ are structurally permissible, and this information pattern results in a *maximin* MPC problem. To illustrate the difference between the minimax and maximin cases, consider the distance function of x^+ from the origin. The optimal minimax distance is attained by control law $u(x) = -x$, and it is equal to 1 for all x , while the optimal maximin distance

is attained by control law $u(x, w) = -x - w$ and it is equal to 0 for all x .

Stochastic MPC considers the case in which a probabilistic information about uncertainty is provided. Typically, uncertainty process is assumed to be stationary and uncorrelated, and stochastic characteristics of the underlying uncertainty are known. For our example, it could be given that $p(w = -1) = 10^{-9}$, $p(w = 1) = 10^{-9}$ and $p(w = 0) = 1 - 2 \cdot 10^{-9}$. In this case, the underlying controlled state process is itself a stochastic process whose essential characteristics can be propagated compatibly with the system equation, employed control functions that should utilize informationally consistent stochastic characteristics of the controlled state process, and prior probabilistic postulates on the initial state. It would be very odd to neglect available stochastic information about uncertainty and implement robust MPC instead of stochastic MPC as well as to compare robust and stochastic MPC, as these belong to mathematically incomparable categories.

In *adaptive MPC*, for a simplified but frequently considered setting, the model of the system, i.e., uncertainty, is unknown and constant. In turn, an implied information about uncertainty is that it actually takes on one of the three possible values $w = -1$, or $w = 0$, or $w = 1$. Any control feedback $u(x)$ allows for learning the value of uncertainty, which is easily deduced from the value of the successor state $w = x^+ - (x + u(x))$. Thus, model uncertainty, in this simplified example, vanishes after one step, and the system becomes purely deterministic after one step. It does not seem appropriate to employ either robust or stochastic MPC as control strategies for adaptive MPC.

Uncertainty Effect on Robust MPC Synthesis

We now dissect the uncertainty effect on robust MPC in a verbose mode and then formally introduce exact robust MPC.

The uncertainty type: The considered uncertainty type is the set-membership uncertainty.

Traditionally, robust MPC treats the minimax case in which, at any time instance k , the state x_k is known, while the values of the current and future uncertainty w_{k+i} are not known but are guaranteed to belong to a known uncertainty constraint set.

The control policy: Under minimax information pattern, state feedback control functions $u_k(\cdot)$, with values $u_k(x_k)$ at states x_k , are structurally permissible and theoretically correct. Thus, within the context of robust MPC, the use of a control policy, which is a sequence of state feedback control functions, is structurally permissible and theoretically flawless.

The generalized state and control predictions: When x and $u(x)$ are the current state and control, the successor state x^+ can take any value in the set of possible successor states, where each possible successor state arises due to a particular uncertainty realization. This set-valued nature of possible successor states propagates through predictions. Consequently, it is necessary to employ generalized predictions in terms of sets of possible states and sets of related control actions.

The controlled dynamics under uncertainty: The controlled dynamics under uncertainty is the dynamics of sets of possible states, which is the controlled set-to-set-dynamics.

The robust constraint satisfaction: The robust constraint satisfaction refers to the requirement that the actual constraints are satisfied for all possible states and associated control actions arising due to all possible uncertainty realizations.

The “worst-case” performance: It is natural to minimize the “worst-case” performance over all uncertainty realizations. The minimization of the “worst-case” performance is done by a selection of a suitable control policy, and it can be also attained by minimization of an adequate, generalized cost function.

The generalized state and control origins: In minimax case of our example, only the stabilization of the state set $\{-1, 0, 1\}$ is possible, and keeping states therein requires control actions from the control set $\{-1, 0, 1\}$. In robust MPC, the state and control origins need to be considered

in a generalized sense as suitably defined state and control sets.

Exact Robust MPC: Contemporary Setting

The system: The most common setting in robust MPC considers the control systems modeled, in discrete time, by:

$$x^+ = f(x, u, w), \quad (1)$$

where $x \in \mathbb{R}^n$, $u \in \mathbb{R}^m$, $w \in \mathbb{R}^p$, and $x^+ \in \mathbb{R}^n$ are, respectively, the current state, control, uncertainty, and the successor state, while $f(\cdot, \cdot, \cdot) : \mathbb{R}^n \times \mathbb{R}^m \times \mathbb{R}^p \rightarrow \mathbb{R}^n$ is the state transition map assumed to be continuous.

The constraints: The system variables x , u , and w are subject to hard constraints:

$$(x, u, w) \in \mathbb{X} \times \mathbb{U} \times \mathbb{W}. \quad (2)$$

The state and control constraint sets $\mathbb{X} \subseteq \mathbb{R}^n$ and $\mathbb{U} \subseteq \mathbb{R}^m$ are assumed to be closed, while the uncertainty constraint set $\mathbb{W} \subset \mathbb{R}^p$ is assumed to be compact.

The control policy: The use of a control policy

$$\Pi_{N-1} := \{\pi_0(\cdot), \pi_1(\cdot), \dots, \pi_{N-1}(\cdot)\}, \quad (3)$$

where N is the prediction horizon and each $\pi_k(\cdot) : \mathbb{R}^n \rightarrow \mathbb{R}^m$ is a control law, is structurally permissible and desirable.

The generalized state and control predictions: The interaction of the uncertainty with the system is captured by invoking the maps $F(\cdot, \cdot)$ and $G(\cdot, \cdot)$ specified, for any subset X of $\mathbb{R}^n$ and any control function $\kappa(\cdot) : \mathbb{R}^n \rightarrow \mathbb{R}^m$, by:

$$\begin{aligned} F(X, \kappa) &:= \{f(x, \kappa(x), w) : x \in X, w \in \mathbb{W}\} \\ \text{and } G(X, \kappa) &:= \{\kappa(x) : x \in X\}. \end{aligned} \quad (4)$$

The state and control predictions are set-valued and, for each relevant k , obey the relations:

$$\begin{aligned} X_{k+1} &= F(X_k, \pi_k) \text{ and } U_k = G(X_k, \pi_k), \text{ with} \\ X_0 &:= \{x\}. \end{aligned} \quad (5)$$

The set sequences $X_N := \{X_0, X_1, \dots, X_{N-1}, X_N\}$ and $U_{N-1} := \{U_0, U_1, \dots, U_{N-1}\}$ represent the predicted sets of possible states and related control actions, and these set sequences are commonly known as the state and control tubes.

The robust constraint satisfaction: The robust constraint satisfaction reduces to the conditions that, for all $k = 0, 1, \dots, N-1$, the set inclusions

$$X_k \subseteq \mathbb{X} \text{ and } U_k \subseteq \mathbb{U} \quad (6)$$

hold true and that the set of possible states X_N at the prediction time instance N satisfies the set inclusion:

$$X_N \subseteq \mathbb{X}_f, \quad (7)$$

where $\mathbb{X}_f \subseteq \mathbb{X}$ is a suitable terminal constraint set.

The terminal constraint set: The terminal constraint set is obtained by considering the uncertain dynamics:

$$x^+ = f(x, \kappa_f(x), w) \quad (8)$$

controlled by a local control function $\kappa_f(\cdot)$. The design of a control law $\kappa_f(\cdot)$ is usually performed offline, and the terminal constraint set $\mathbb{X}_f$ accounts locally for the state and control constraints. The terminal constraint set $\mathbb{X}_f$ is assumed to be closed and robust positively invariant for the dynamics (8) and constraint sets (2). Thus, the set $\mathbb{X}_f$ and a local control function $\kappa_f(\cdot)$ satisfy:

$$\begin{aligned} F(\mathbb{X}_f, \kappa_f) &\subseteq \mathbb{X}_f \subseteq \mathbb{X} \text{ and} \\ \mathbb{U}_f &:= G(\mathbb{X}_f, \kappa_f) \subseteq \mathbb{U}. \end{aligned} \quad (9)$$

The best choice for $\mathbb{X}_f$ is the maximal robust positively invariant set for the dynamics (8) and constraint sets (2).

The generalized origin: The most natural candidate for the generalized origin is a minimal

robust positively invariant set for the dynamics (8) and constraint sets (2). This set is entirely determined by the associated state set–dynamics

$$X^+ = F(X, \kappa_f). \quad (10)$$

The minimal robust positively invariant set is compact and well defined in the case when the local control function $\kappa_f(\cdot)$ ensures that the corresponding map $F(\cdot, \kappa_f)$ is a contraction over the space of compact subsets of $\mathbb{X}_f$ (Artstein and Raković 2008), in which case it is the unique solution to the fixed point set equation:

$$X = F(X, \kappa_f), \quad (11)$$

and it is an exponentially stable attractor for the state set–dynamics (10) with the basin of attraction being the space of compact subsets of $\mathbb{X}_f$. Thus, the usual $(0, 0)$ fixed-point pair is replaced by the fixed-point pair of sets $(\mathbb{X}_O, \mathbb{U}_O)$ satisfying:

$$\begin{aligned} \mathbb{X}_O &= F(\mathbb{X}_O, \kappa_f) \subseteq \mathbb{X}_f \text{ and} \\ \mathbb{U}_O &:= G(\mathbb{X}_O, \kappa_f) \subseteq \mathbb{U}_f. \end{aligned} \quad (12)$$

The generalized cost function: The stage cost function $\ell(\cdot, \cdot) : \mathbb{X} \times \mathbb{U} \rightarrow \mathbb{R}_+$ is continuous and adequately lower bounded with respect to the generalized origin $\mathbb{X}_O$ so that, for all $x \in \mathbb{X}$ and all $u \in \mathbb{U}$,

$$\alpha_1(\text{dist}(\mathbb{X}_O, x)) \leq \ell(x, u), \quad (13)$$

where $\alpha_1(\cdot)$ is a $\mathcal{K}_\infty$ –class function and $\text{dist}(\mathbb{X}_O, \cdot)$ is the distance function from the set $\mathbb{X}_O$. The consideration of the generalized origin requires the condition that for all $x \in \mathbb{X}_O$ the use of local control function $\kappa_f(\cdot)$ is “free of charge” with respect to $\ell(\cdot, \cdot)$, i.e., that for all $x \in \mathbb{X}_O$ we have:

$$\ell(x, \kappa_f(x)) = 0. \quad (14)$$

The terminal cost function $V_f(\cdot)$ is assumed to be continuous and adequately upper bounded with respect to the generalized origin $\mathbb{X}_O$ so that, for all $x \in \mathbb{X}_f$,

$$V_f(x) \leq \alpha_2(\text{dist}(\mathbb{X}_O, x)), \quad (15)$$

where, as above, $\alpha_2(\cdot)$ is a $\mathcal{K}_\infty$ –class function. In addition, the terminal cost function $V_f(\cdot)$ satisfies locally a usual condition for robust stabilization, so that, for all $x \in \mathbb{X}_f$ and all $w \in \mathbb{W}$,

$$V_f(f(x, \kappa_f(x), w)) - V_f(x) \leq -\ell(x, \kappa_f(x)). \quad (16)$$

The cost function $V_N(\cdot, \cdot, \cdot)$ is defined, for all $x \in \mathbb{X}$, all Π_{N-1} and all $\mathbf{w}_{N-1} := \{w_0, w_1, \dots, w_{N-1}\}$, by

$$V_N(x, \Pi_{N-1}, \mathbf{w}_{N-1}) := \sum_{k=0}^{N-1} \ell(x_k, u_k) + V_f(x_N), \quad (17)$$

where $u_k := \pi_k(x_k)$ and $x_k := x_k(x, \Pi_{N-1}, \mathbf{w}_{N-1})$ denote the solution of (1) when the initial state is x , control policy is Π_{N-1} and uncertainty realization is $\mathbf{w}_{N-1}$.

The exact ROC: The exact ROC problem $\mathbb{P}_N(x)$, $x \in \mathbb{X}$, takes the form of an infinite-dimensional minimaximization:

$$\begin{aligned} J_N(x, \Pi_{N-1}) &:= \max_{\mathbf{w}_{N-1} \in \mathbb{W}^N} V_N(x, \Pi_{N-1}, \mathbf{w}_{N-1}), \\ V_N^0(x) &:= \min_{\Pi_{N-1} \in \mathbf{\Pi}_{N-1}(x)} J_N(x, \Pi_{N-1}), \\ \Pi_{N-1}^0(x) &\in \arg \min_{\Pi_{N-1} \in \mathbf{\Pi}_{N-1}(x)} J_N(x, \Pi_{N-1}), \end{aligned} \quad (18)$$

where $\mathbf{\Pi}_{N-1}(x)$ denotes the set of the constraint admissible control policies defined, for all $x \in \mathbb{X}$, by:

$$\mathbf{\Pi}_{N-1}(x) := \{\Pi_{N-1} : \text{conditions (5)–(7) hold}\}. \quad (19)$$

With the intended scope of this article in mind, it is assumed that the infinite-dimensional minimaximization is well posed and that the value function $V_N^0(\cdot)$ admits an upper bound in terms of a suitable $\mathcal{K}_\infty$ –class function as specified in (23).

The value function $V_N^0(\cdot)$ might admit nonunique optimal control policies, so that $\Pi_{N-1}^0(\cdot)$ represents a selection from the set of optimal control policies. The effective domain

$\mathcal{X}_N$ of the value function $V_N^0(\cdot)$ and optimal control policy $\Pi_{N-1}^0(\cdot)$,

$$\mathcal{X}_N := \{x \in \mathbb{R}^n : \Pi_{N-1}(x) \neq \emptyset\} \quad (20)$$

is known in the literature as the N -step minimax controllable set to a target set $\mathbb{X}_f$, and it is such that $\mathbb{X}_f \subseteq \mathcal{X}_N \subseteq \mathbb{X}$.

The exact robust MPC: The exact robust MPC implements values of the control law $\pi_0^0(\cdot)$. The control law $\pi_0^0(\cdot)$ is well defined for all $x \in \mathcal{X}_N$, and it induces the controlled uncertain dynamics specified, for all $x \in \mathcal{X}_N$, by:

$$x^+ \in \mathcal{F}(x), \quad \mathcal{F}(x) := \{f(x, \pi_0^0(x), w) : w \in \mathbb{W}\}. \quad (21)$$

The robust MPC law $\pi_0^0(\cdot)$ renders the N -step minimax controllable set $\mathcal{X}_N$ robust positively invariant so that, for all $x \in \mathcal{X}_N$,

$$\mathcal{F}(x) \subseteq \mathcal{X}_N \subseteq \mathbb{X} \text{ and } \pi_0^0(x) \in \mathbb{U}. \quad (22)$$

Furthermore, the associated value function $V_N^0(\cdot) : \mathcal{X}_N \rightarrow \mathbb{R}_+$ is, by construction, a Lyapunov certificate verifying the robust asymptotic stability of the generalized origin $\mathbb{X}_\mathcal{O}$ for the controlled uncertain dynamics (21) with the basin of attraction being equal to the N -step minimax controllable set $\mathcal{X}_N$. More precisely, for all $x \in \mathcal{X}_N$, it holds that:

$$\alpha_1(\text{dist}(\mathbb{X}_\mathcal{O}, x)) \leq V_N^0(x) \leq \alpha_3(\text{dist}(\mathbb{X}_\mathcal{O}, x)), \quad (23)$$

where $\alpha_3(\cdot)$ is postulated $\mathcal{K}_\infty$ -class function, while for all $x \in \mathcal{X}_N$ and all $x^+ \in \mathcal{F}(x)$, it holds that:

$$V_N^0(x^+) - V_N^0(x) \leq -\alpha_1(\text{dist}(\mathbb{X}_\mathcal{O}, x)). \quad (24)$$

Under reasonable conditions, exact robust MPC induces strong structural properties, but its computational complexity is overwhelming. However, in the preceding formulation, uncertainty effects have been “dissected,” and the “basic building blocks” employed for exact robust MPC have been identified.

Alternative Approaches to Robust MPC

Inherent Robustness of MPC

An approach to robust MPC can be derived by attempting to utilize inherent robustness of conventional MPC, see, e.g., Limon et al. (2009) and related references. Such approach is an indirect approach to robust MPC, and it is computationally feasible. This approach considers a nominal MPC possibly applied to modified model, constraints, and cost, and when possible it makes use of robustness of its stability properties. The approach might be well suited for problems with neither state nor terminal constraints. However, the robustness properties can be very limited in terms of the magnitude of tolerable uncertainty. In addition, the related robustness analysis is unnecessarily conservative and geometrically insensitive, i.e., it is of very little value for optimal state trajectories on, or near, the boundaries of the state constraints. Major drawbacks of such an approach, however, stem from the facts that the stability property of the conventional MPC might fail to be robust (Grimm et al. 2004) and that the optimal control of constrained discrete time systems can be a fragile process itself (Raković 2009).

Scenario-Based Approaches for Robustness

The approach based on utilization of scenarios of uncertainty realizations is particularly very well suited for the case of linear systems with convex cost functions subject to convex constraints and when the uncertainty set is specified as the convex hull of finitely many points (Scokaert and Mayne 1998). In this approach, with each of finitely many extreme uncertainty realizations, a pair of “extreme” state and control sequences is associated. The collection of all pairs of such “extreme” state and control sequences is optimized subject to dynamical constraints (which are deterministic since uncertainty realizations are postulated), causality constraints, and state, control, and terminal constraints. This approach converts the infinite-dimensional minimaximization

tion into an equivalent finite-dimensional minimaximization, but it remains computationally intractable due to an exponential increase of the number of extreme uncertainty realizations with respect to the prediction horizon.

Some recent proposals consider a limited number of uncertainty realizations, and related scenarios are constructed by allowing uncertainty to vary over a shorter horizon, while uncertainty is considered constant over the remainder of the prediction horizon. Such approaches enhance computational aspects and can be used in more general settings, see, e.g., Lucia et al. (2012) and related references. Theoretically, it is difficult to justify the postulated structural restriction on the scenarios of uncertainty realizations. Furthermore, it is highly unlikely for such approaches to guarantee a priori any of the desirable structural properties, as provided by alternative robust MPC methods.

A very promising approach is to deploy scenario-based optimization for robust MPC (Calafiore and Campi 2006; Calafiore and Fagiano 2013), in which uncertainty is sampled in a traditional manner. These approaches provide probabilistic guarantees of structural properties that are strictly weaker than the absolute ones guaranteed by robust MPC.

Parameterized Predictions and Control Policy

The parameterization of state and control predictions as well as control policy has led to major advances in robust MPC. The core simplification in these approaches is the use of finite-dimensional parameterization of control policy. The control policy is parameterized so as to allow for the utilization of both the least conservative parameterized state and control predictions and a range of simpler, but sensible, cost functions. The computational complexity of the exact state and control tubes is tackled by employing implicit representations of the predicted sets of possible states and control actions. Alternatively, simpler outer-bounding approximations of the exact state and control tubes are deployed, and the exact set-dynamics of the state and control tubes (5) is relaxed to

$$\{x_0\} \subseteq X_0, \text{ and } F(X_k, \pi_k) \subseteq X_{k+1}$$

$$\text{and } G(X_k, \pi_k) \subseteq U_k.$$

The terminal constraint set $\mathbb{X}_f$ is deployed as computationally feasible and “relaxed form” of the generalized state origin $\mathbb{X}_O$. The performance requirements are carefully prioritized, and modified when necessary, and expressed in terms of the cost functions that do not require intractable minimax optimization but still ensure that the associated value function verifies the robust stability and attractivity of the generalized origin $\mathbb{X}_O$ or the terminal constraint set $\mathbb{X}_f$.

Tube MPC

A new paradigm in robust MPC that has effectively defined modern robust MPC is tube MPC. Tube MPC has been pioneered and advanced primarily through joint and individual research activities of David Q. Mayne and Saša V. Raković. For completeness, we provide a brief overview of tube MPC for linear systems subject to bounded additive uncertainty

$$x^+ = Ax + Bu + w. \quad (25)$$

In what follows, $\oplus$ denotes the Minkowski set addition, while $\ominus$ denotes the Pontryagin set difference.

Rigid Tube MPC

In rigid tube MPC, introduced and discussed in detail in Mayne et al. (2005), state and control predictions are parameterized as

$$x_k = z_k + s_k \text{ and } u_k = v_k + K s_k, \quad (26)$$

and state feedback control laws of related control policy are

$$\pi_k(x_k, z_k, v_k) = v_k + K(x_k - z_k). \quad (27)$$

The sets forming state and control tubes are parameterized as

$$X_k = z_k \oplus S \text{ and } U_k = v_k \oplus KS. \quad (28)$$

The state tube cross-sectional shape set S is assumed to be robust positively invariant set for $s^+ = (A + BK)s + w$, i.e.,

$$(A + BK)S \oplus \mathbb{W} \subseteq S. \quad (29)$$

Rigid tube MPC is computationally efficient since it reduces to a conventional MPC for a virtual deterministic linear system

$$z_{k+1} = Az_k + Bv_k \quad (30)$$

subject to modified constraints

$$z_k \in \mathbb{Z} := \mathbb{X} \ominus S \text{ and } v_k \in \mathbb{V} := \mathbb{U} \ominus KS, \quad (31)$$

and suitable terminal constraints $z_N \in \mathbb{Z}_f$ as well as uncertainty free stage and terminal cost functions $\ell(\cdot, \cdot)$ and $V_f(\cdot)$ with values $\ell(z_k, v_k)$ and $V_f(z_N)$. Rigid tube MPC enables a flexible selection of free initial condition of the virtual system

$$x - z_0 \in S \quad (32)$$

at any state x . This condition proves to be a key ingredient in establishing robust exponential stability of the set S for uncertain dynamics controlled by rigid tube MPC $u_0^0(x) = v_0^0(x) + K(x - z_0^0(x))$, based on the exponential stability of the origin for the virtual system $z^+(x) = Az_0^0(x) + Bv_0^0(x)$.

Homothetic Tube MPC

Homothetic tube MPC (Raković et al. 2012, 2013) relaxes rigidity of state and control tubes parameterization in (28) by deploying state and control tubes whose terms are parameterized as

$$X_k = z_k \oplus \alpha_k S \text{ and } U_k = v_k \oplus \alpha_k KS, \quad (33)$$

where nonnegative scalars $\alpha_k \in \mathbb{R}_{\geq 0}$ are referred to as the state and control tubes scaling factors. The exact set-dynamics of the state tubes is utilized, and it is expressed as

$$Az_k + Bv_k + \alpha_k(A + BK)S \oplus \mathbb{W}$$

$$\subseteq z_{k+1} \oplus \alpha_{k+1} S, \quad (34)$$

while state and control constraints take form

$$z_k \oplus \alpha_k S \subseteq \mathbb{X} \text{ and } v_k \oplus \alpha_k KS \subseteq \mathbb{U}, \quad (35)$$

and adequate terminal constraints $(z_N, \alpha_N) \in \Omega_f$ as well as uncertainty free stage and terminal cost functions $\ell(\cdot, \cdot, \cdot)$ and $V_f(\cdot, \cdot)$ with values $\ell(z_k, v_k, \alpha_k)$ and $V_f(z_N, \alpha_N)$. The selection of z_0 and α_0 is governed by

$$x - z_0 \in \alpha_0 S. \quad (36)$$

Homothetic tube MPC, a detailed summary of which can be found in Raković et al. (2012, 2013), enlarges domain of attraction and improves attractivity properties compared to rigid tube MPC.

Elastic Tube MPC

Elastic tube MPC (Raković et al. 2016) further relaxes rigidity and homotheticity of tubes parameterizations in (28) and (33). In elastic tube MPC, the state tube cross-sectional shape set is, in fact, a value of a set-valued function $S(\cdot)$ given, for all $a \in \mathbb{R}_{\geq 0}^q$, by

$$S(a) := \{x : Cx \leq a\}, \quad (37)$$

where a suitable matrix $C \in \mathbb{R}^{q \times n}$ is constructed offline. The terms of state and control tubes are parameterized as

$$X_k = z_k \oplus S(a_k) \text{ and } U_k = v_k \oplus KS(a_k), \quad (38)$$

where nonnegative variables a_k are referred to as the state and control tubes elasticity factors. The exact set-dynamics of the state tubes is given by

$$\begin{aligned} & Az_k + Bv_k + (A + BK)S(a_k) \oplus \mathbb{W} \\ & \subseteq z_{k+1} \oplus S(a_{k+1}), \end{aligned} \quad (39)$$

while state and control constraints take form

$$z_k \oplus S(a_k) \subseteq \mathbb{X} \text{ and } v_k \oplus KS(a_k) \subseteq \mathbb{U}, \quad (40)$$

and suitable terminal constraints $(z_N, a_N) \in \Omega_f$ as well as uncertainty free stage and terminal cost functions $\ell(\cdot, \cdot, \cdot)$ and $V_f(\cdot, \cdot)$ with values $\ell(z_k, v_k, a_k)$ and $V_f(z_N, a_N)$. To ensure computational practicability, guaranteed and convex reformulations of set-dynamics (39) and state and control constraints (40) are utilized, while z_0 and a_0 satisfy

$$x - z_0 \in S(a_0). \quad (41)$$

Elastic tube MPC enlarges domain of attraction and improves attractivity properties relative to both the homothetic and rigid tube MPC. See Raković et al. (2016) for more details about elastic tube MPC.

Tube MPC with Time-Varying Cross Sections

Robust MPC based on constraint tightening proposed in Chisci et al. (2001) can be seen as a tube MPC with time-varying cross sections, since related sets of possible state and controls take the form

$$X_k = z_k \oplus S_k \text{ and } U_k = v_k \oplus K S_k, \quad (42)$$

where

$$S_{k+1} = (A + BK)S_k \oplus \mathbb{W}. \quad (43)$$

As proposed in Chisci et al. (2001), this form of tube MPC utilizes virtual system (30) and time-varying state and control constraints

$$z_k \in \mathbb{Z}_k := \mathbb{X} \ominus S_k \text{ and } v_k \in \mathbb{V}_k := \mathbb{U} \ominus K S_k, \quad (44)$$

and terminal constraints $z_N \oplus S_N \subseteq \mathbb{X}_f$ where $\mathbb{X}_f$ is the maximal robust positively invariant set for $s^+ = (A + BK)s + w$ and constraints $(s, Ks) \in \mathbb{X} \times \mathbb{U}$ and $w \in \mathbb{W}$. The proposal of Chisci et al. (2001) minimizes the cost in terms of “control perturbations” $c_k = v_k + K z_k$, and it enforces a restrictive constraint on the initial states $z_0 = x$, i.e., $S_0 = \{0\}$, which prevents robust exponential stability to be established. However, this proposal can be modified to include selection of initial condition of the virtual system via $x - z_0 \in \mathbb{X}_f$

in analogy to (32), which would enable robust exponential stability to be verified.

Tube MPC with Optimized Time-Varying Cross Sections

A further contribution to robust MPC is made in Löfberg (2003) and Goulart et al. (2006), where the so-called affine in the past disturbances control policy is utilized. Within the context of tube MPC, the related parameterizations of predicted states and controls are

$$\begin{aligned} x_k &= z_k + \sum_{j=1}^k T_{(j,k)} w_j \text{ and} \\ u_k &= v_k + \sum_{j=1}^k M_{(j,k)} w_j, \end{aligned} \quad (45)$$

where matrices $T_{(j,k)}$ and $M_{(j,k)}$ are decision variables and the related sets of possible states and controls take the form

$$\begin{aligned} X_k &= z_k \oplus \bigoplus_{j=1}^k T_{(j,k)} \mathbb{W} \text{ and} \\ U_k &= v_k \oplus \bigoplus_{j=1}^k M_{(j,k)} \mathbb{W}. \end{aligned} \quad (46)$$

The state tube dynamics is governed by deterministic z -dynamics (30) and matrix-valued $T_{(j,k)}$ -dynamics

$$T_{(j,k+1)} = AT_{(j,k)} + BM_{(j,k)} \text{ with } T_{(j,j)} = I. \quad (47)$$

The state and control constraints are given by

$$\begin{aligned} z_k \oplus \bigoplus_{j=1}^k T_{(j,k)} \mathbb{W} &\subseteq \mathbb{X} \text{ and} \\ v_k \oplus \bigoplus_{j=1}^k M_{(j,k)} \mathbb{W} &\subseteq \mathbb{U}, \end{aligned} \quad (48)$$

and terminal constraints are $z_N \oplus \bigoplus_{j=1}^N T_{(j,N)} \mathbb{W} \subseteq \mathbb{X}_f$. The polyhedral state, control, and terminal constraints can be efficiently

handled by using support functions and duality. A range of uncertainty free cost functions can be utilized to design a robust exponentially stable tube MPC via efficient online optimization of the uncertainty free states z_k and controls v_k and collections of matrices $T_{(j,k)}$ and $M_{(j,k)}$.

Parameterized Tube MPC

The current state of the art in robust MPC is parameterized tube MPC (Raković 2012; Raković et al. 2012), which employs superposition and convex decomposition for predictions of states and controls

$$x_k = \sum_{j=0}^k x_{(j,k)} \text{ and } u_k = \sum_{j=0}^k u_{(j,k)}, \text{ with } (49)$$

$$x_{(j,k)} = \sum_{i=0}^q \lambda_i x_{(i,j,k)} \text{ and } u_{(j,k)} = \sum_{i=0}^q \lambda_i u_{(i,j,k)}, \quad (50)$$

via partial extreme states and controls $x_{(0,k)}$, $x_{(i,j,k)}$, $u_{(0,k)}$, and $u_{(i,j,k)}$, and where $\lambda_i = \lambda_{(i,j,j)}$ are convex multipliers. The sets of possible states and controls take the form

$$X_k = \bigoplus_{j=0}^k X_{(j,k)} \text{ and } U_k = \bigoplus_{j=0}^k U_{(j,k)}, \quad (51)$$

where partial state and control tubes cross sections are given as $X_{(0,k)} = \{x_{(0,k)}\}$, $X_{(j,k)} = \text{convh}(\{x_{(1,j,k)}, x_{(2,j,k)}, \dots, x_{(q,j,k)}\})$, $U_{(0,k)} = \{u_{(0,k)}\}$, and $U_{(j,k)} = \text{convh}(\{u_{(1,j,k)}, u_{(2,j,k)}, \dots, u_{(q,j,k)}\})$. The exact set-dynamics of the state tubes is governed by deterministic extreme partial states dynamics specified by

$$\begin{aligned} x_{(0,k+1)} &= Ax_{(0,k)} + Bu_{(0,k)} \text{ with } x_{(0,0)} = x \text{ and} \\ x_{(i,j,k+1)} &= Ax_{(i,j,k)} + Bu_{(i,j,k)} \text{ with } x_{(i,j,j)} = \bar{w}_i, \end{aligned} \quad (52)$$

where $\mathbb{W} = \text{convh}(\{\bar{w}_1, \bar{w}_2, \dots, \bar{w}_q\})$. The state and control constraints are given by

$$\bigoplus_{j=0}^k X_{(j,k)} \subseteq \mathbb{X} \text{ and } \bigoplus_{j=0}^k U_{(j,k)} \subseteq \mathbb{U}, \quad (53)$$

and terminal constraints are $\bigoplus_{j=0}^N X_{(j,N)} \subseteq \mathbb{X}_f$. The polyhedral state, control, and terminal constraints can be efficiently handled by using support functions without need to perform any of Minkowski set additions and convex hull operations utilized for parameterization and analysis. A range of uncertainty free cost functions can be utilized to design a robust exponentially stable tube MPC via efficient online optimization of the sequences of extreme partial states $x_{(0,k)}$ and $x_{(i,j,k)}$ and extreme partial controls $u_{(0,k)}$ and $u_{(i,j,k)}$. Parameterized tube MPC outperforms proposals of Löfberg (2003) and Goulart et al. (2006), as it uses separable nonlinear state feedback control functions.

Closing Remarks and Recommended Reading

The exact robust MPC synthesis has reached a remarkable degree of theoretical maturity in the general setting. Furthermore, a variety of rather sophisticated robust MPC synthesis methods, which are both computationally efficient and theoretically sound, has been developed for the frequently encountered linear-polyhedral case. The further advances in the robust MPC field should be driven by the utilization of more structured types and models of the uncertainty. Given a tremendous progress in robust MPC and its successful utilization across a number of control engineering areas, a comprehensive survey of this field is definitely due.

The comprehensive monograph (Rawlings and Mayne 2009) provides an in-depth systematic exposure to MPC and robust MPC, and it is also a rich source of relevant references. The invaluable overview of the theory and computations of the maximal and minimal robust positively invariant sets can be found in Kolmanovsky and Gilbert (1998) and Artstein and Raković (2008). The important work Scokaert and Mayne (1998) points out the theoretical benefits of the use of the control policy, but it also indicates indirectly the computational impracticability of the associated feedback minimax robust

MPC. The early tube MPC synthesis (Langson et al. 2004; Mayne et al. 2005) represent key steps forward in robust MPC for the linear–polyhedral setting. Homothetic and elastic tube MPC syntheses (Raković et al. 2012, 2013, 2016) provide a number of improvements relative to the first generation of tube MPC (Mayne et al. 2005), and these methods have a high potential to effectively handle the parametric uncertainty of the matrix pair (A, B) . The current state of the art in the linear–polytopic setting is reached by parameterized tube MPC (Raković 2012; Raković et al. 2012). The output feedback robust MPC synthesis in the linear–polyhedral setting can be handled with direct extensions of the tube MPC syntheses (Mayne et al. 2006, 2009).

Minneapolis, MN, USA

²Mechanical Engineering Department,
University of California, Berkeley, CA, USA

Abstract

This entry provides a brief summary of the synthesis and analysis tools that have been developed by the robust control community. Many software tools have been developed to implement the major theoretical techniques in robust control. These software tools have enabled robust synthesis and analysis techniques to be successfully applied to numerous industrial applications.

Keywords

Integral quadratic constraint · Linear matrix inequality · Model uncertainty · Robust control toolbox · Structured singular values

Introduction

Robust control is a methodology to address the effect of uncertainty on feedback systems. This approach includes techniques and tools to model system uncertainty, assess stability and/or performance characteristics of the uncertain system, and synthesize controllers for uncertain systems. The theory was developed over a number of years. The foundational results can be found in classical papers Packard and Doyle (1993a), Desoer et al. (1980), Doyle (1978, 1982), Doyle et al. (1989), Doyle and Stein (1981), Megretski and Rantzer (1997), Safonov (1982), Willems (1971), and Zames (1981)

and more recent textbooks Boyd et al. (1994), Desoer and Vidyasagar (2008), Dullerud and Paganini (2000), Francis (1987), Skogestad and Postlethwaite (2005), Vidyasagar (1985), and Zhou et al. (1996). It should be emphasized that this entry is not meant to be a survey and more complete references to the literature can be found in the cited textbooks. The remainder of this entry discusses the main theoretical and computational tools for robust synthesis and robustness analysis.

Notation

$\mathbf{R}$ and $\mathbf{C}$ denote the set of real and complex numbers, respectively. $\mathbf{R}^{m \times n}$ and $\mathbf{C}^{m \times n}$ denote the sets of $m \times n$ matrices whose elements are in $\mathbf{R}$ and $\mathbf{C}$, respectively. A single superscript index is used for vectors, e.g., $\mathbf{R}^n$ denotes the set of $n \times 1$ vectors whose elements are in $\mathbf{R}$. For a matrix $M \in \mathbf{C}^{m \times n}$, M^T denotes the transpose and M^* denotes the complex conjugate transpose. A matrix M is Hermitian (Skew-Hermitian) if $M = M^*$ ($M = -M^*$). The maximum singular value of a matrix M is denoted by $\bar{\sigma}(M)$. The trace of a matrix M , denoted $\text{tr}[M]$, is the sum of the diagonal elements. $M = M^*$ is a positive semidefinite matrix, denoted $M \succeq 0$, if all eigenvalues are nonnegative. $M = M^*$ is negative semidefinite, denoted $M \preceq 0$, if $-M \succeq 0$. $\mathcal{L}_2^n[0, \infty)$ is the space of functions $u : [0, \infty) \rightarrow \mathbf{R}^n$ satisfying $\|u\| < \infty$ where $\|u\| := \left[\int_0^\infty u(t)^T u(t) dt \right]^{0.5}$. For $u \in \mathcal{L}_2^n[0, \infty)$, u_T denotes the truncated function $u_T(t) = u(t)$ for $t \leq T$ and $u(t) = 0$ otherwise. The extended space, denoted $\mathcal{L}_{2e}$, is the set of functions u such that $u_T \in \mathcal{L}_2$ for all $T \geq 0$. The Fourier transform $\hat{v} := \mathcal{F}(v)$ maps the time domain signal $v \in \mathcal{L}_2^n[0, \infty)$ to the frequency domain by

$$\hat{v}(j\omega) := \int_0^\infty e^{-j\omega t} v(t) dt \quad (1)$$

Capital letters are used to represent dynamical systems. For linear systems, the same letter is used to represent the system, its convolution kernel, as well as its frequency-response function. Lowercase letters denote time-signals, and

ω represents the continuous-time frequency variable. For an $m \times n$ system G , define the H_∞ and H_2 norms as $\|G\|_\infty = \sup_\omega \bar{\sigma}(G(j\omega))$ and $\|G\|_2 = \sqrt{\frac{1}{2\pi} \int_{-\infty}^{\infty} \text{tr}[G(j\omega)^* G(j\omega)] d\omega}$. The $\mathcal{L}_1$ norm of G is defined as $\|G\|_1 = \max_{1 \leq i \leq m} \sum_{j=1}^n \int_0^\infty |g_{ij}(t)| dt$ where $g_{ij}(t)$ is the response of the i th output due to a unit impulse in the j th input. The entry describes continuous-time systems. Most results carry over, in a similar form, to discrete-time systems.

Theoretical Tools

Uncertainty Modeling

In order to analyze and/or design for the degrading effects of uncertainty, it is imperative that explicit models of uncertainty be characterized. Two distinct forms of uncertainty are considered: signal uncertainty and model uncertainty. Signal uncertainty represents external signals (plant disturbances, sensor noise, reference signals) as sets of time functions, with explicit descriptions. For example, a particular reference input might be characterized as belonging to the set $\left\{ \frac{4}{2s+1} d : d \in \mathcal{L}_2, \|d\|_2 \leq 1 \right\}$. This set is often referred to as a *weighted ball in $\mathcal{L}_2$* . The transfer function $\frac{4}{2s+1}$ is called a *weighting function* and it shapes the normalized signals d , in a manner that its output represents the actual traits of the reference inputs that occur in practice.

Model uncertainty represents unknown or partially specified gains (more generally, operators) that relate pairs of signals in the model. For example, z and w are signals within a model and are related by an operator $\mathcal{N}$ as $w = \mathcal{N}(z)$. Typical partial specifications either constrain $\mathcal{N}$ to be drawn from a specified set or describe the set of signals (w, z) that $\mathcal{N}$ allows. An *uncertain parameter* δ is modeled as time-invariant (i.e., constant), belonging to the interval $[a, b]$ and relating z and w as $w(t) = \delta z(t)$. An *uncertain linear dynamic element*, Δ is modeled as linear, time-invariant, causal system, described by a convolution kernel δ whose frequency-response function (i.e., Fourier transform) satisfies $\max_\omega |\hat{\delta}(j\omega)| \leq 1$, and relating z and

w as $w = \delta \star z$. More generally, consider an $\mathcal{L}_2$ bounded, causal operator, mapping $\mathcal{L}_{2,e} \rightarrow \mathcal{L}_{2,e}$ relating the signals as $w = \Delta(z)$. The behavior of Δ is unknown but constrained by a family of multipliers, $\{\Pi_\alpha\}_{\alpha \in \mathcal{A}}$. Specifically, each Π_α is a Hermitian, matrix-valued function of frequency, and for any $z \in \mathcal{L}_2$, the mapping Δ is known to satisfy

$$\int_{-\infty}^{\infty} \begin{bmatrix} \hat{z}(j\omega) \\ \hat{w}(j\omega) \end{bmatrix}^* \Pi_\alpha(\omega) \begin{bmatrix} \hat{z}(j\omega) \\ \hat{w}(j\omega) \end{bmatrix} d\omega \geq 0$$

This is called an *integral quadratic constraint* (IQC) description of Δ , as the input/output pairs of Δ satisfy a family of quadratic, integral constraints. These different descriptions of model uncertainty are related. For example, if $w(t) = \delta z(t)$, with $w(t) \in \mathbf{R}^n$ and $z(t) \in \mathbf{R}^n$, and $\delta \in \mathbf{R}$, $|\delta| \leq 1$, then for any Hermitian-valued $X : \mathbf{R} \rightarrow \mathbf{C}^{n \times n}$ with $X(\omega) \geq 0$ for all $\omega \in \mathbf{R}$ and Skew-Hermitian $Y : \mathbf{R} \rightarrow \mathbf{C}^{n \times n}$,

$$\begin{aligned} \int_{-\infty}^{\infty} \begin{bmatrix} \hat{z}(j\omega) \\ \hat{w}(j\omega) \end{bmatrix}^* \begin{bmatrix} X(\omega) & Y(\omega) \\ Y^*(\omega) & -X(\omega) \end{bmatrix} \begin{bmatrix} \hat{z}(j\omega) \\ \hat{w}(j\omega) \end{bmatrix} d\omega \\ = \int_{-\infty}^{\infty} \hat{z}^*(j\omega) \left[(1 - \delta^2) X(\omega) \right] \hat{z}(j\omega) d\omega \end{aligned}$$

which is always ≥ 0 . Hence, the *uncertain parameter* can be recast as an operator satisfying an infinite family of IQCs. Nonlinear operators may also satisfy IQCs and it is common to “model” known nonlinear elements (e.g., saturation) by enumerating IQCs that they satisfy (Megretski and Rantzer 1997). An *uncertain dynamic model* is made up of an interconnection of these uncertain elements with a known (usually) linear system G .

Performance Metric

The main goal of robustness analysis is to assess the degrading effects of uncertainty. For this, a concrete notion of performance is needed, resulting in a mathematical/computational exercise to quantify the average or worst-case effects of the two types of uncertainty, signal and model, described earlier. In the robust control framework, adequate performance is

characterized in terms of the variability of possible behavior of particular signals. For instance, in the presence of reference inputs and disturbance inputs, as well as parameter uncertainty, it is required that tracking errors (e) and control inputs (u) remain small. A common measure of smallness is the $\mathcal{L}_2$ norm of signals. Typically, frequency-dependent weighting functions are used to preferentially weight one frequency range over another and/or to weight one signal relative to another. In this way, adequate performance can be defined as $\|W \begin{bmatrix} e \\ u \end{bmatrix}\|_2 \leq 1$, where W is a stable, linear system, called the “output” weighting function. Weighting functions are often used to transform a collection of performance objectives into a single norm bound objective in the robust control framework.

Robustness Analysis

Robustness analysis refers to the task of ascertaining the stability and/or performance characteristics of the uncertain system, given the limited knowledge about the uncertain information. The main result from Megretski and Rantzer (1997) concerns the stability of the interconnection shown in Fig. 1, where G is a known, stable, linear system and Δ is an operator that satisfies the IQC defined by Π . Under some important technical conditions, the theorem states “if there exists an $\epsilon > 0$ such that

$$\begin{bmatrix} G(j\omega) \\ I \end{bmatrix}^* \Pi(\omega) \begin{bmatrix} G(j\omega) \\ I \end{bmatrix} \leq -\epsilon I \quad (2)$$

for all $\omega \in \mathbf{R}$, then the interconnection is stable.” Stability here refers to finite $\mathcal{L}_2$ gain from inputs (r_1, r_2) to loop signals (u_1, u_2) .

Multiple IQCs satisfied by Δ can be incorporated into the analysis. In particular, assume that Δ satisfies the IQCs defined by the multipliers $\{\Pi_k\}_{k=1}^N$. Then Δ satisfies the IQC defined by any multiplier of the form $\Pi^\alpha := \sum_{k=1}^N \alpha_k \Pi_k$ where $\alpha_k \geq 0$. The stability test amounts to a semi-infinite, semidefinite feasibility problem: find nonnegative scalars $\{\alpha_k\}_{k=1}^N$ such that for some $\epsilon > 0$,

Robust Synthesis and Robustness Analysis Techniques and Tools, Fig. 1 Feedback interconnection for IQC stability test

$$\begin{bmatrix} G(j\omega) \\ I \end{bmatrix}^* \Pi^\alpha(\omega) \begin{bmatrix} G(j\omega) \\ I \end{bmatrix} \leq -\epsilon I \quad (3)$$

for all $\omega \in \mathbf{R}$. This infinite family of matrix inequalities (one for each frequency) can be equivalently expressed as a finite-dimensional linear matrix inequality (LMI) under some additional restrictions.

The structured singular value (μ) approach provides an alternative robust stability test in the case of only linear, time-invariant uncertainty (parametric or dynamic). Suppose Δ is drawn from a set of matrices, $\mathbf{\Delta} \subseteq \mathbf{C}^{m \times n}$ of the form

$$\mathbf{\Delta} = \left\{ \text{diag} \left[\delta_1^r I_{I_1}, \dots, \delta_V^r I_{I_V}, \delta_1^c I_{I_1}, \dots, \delta_S^c I_{I_S}, \Delta_1, \dots, \Delta_F \right] : \begin{array}{l} \delta_k^r \in \mathbf{R}, \delta_i^c \in \mathbf{C}, \Delta_j \in \mathbf{C}^{m_j \times n_j} \end{array} \right\}$$

The inclusion of complex-valued, uncertain matrices within $\mathbf{\Delta}$ may seem unusual and hard to motivate. However, in terms of their effect on stability, these are equivalent to the *uncertain linear dynamic element* introduced earlier in the *Uncertainty Modeling* section. This is discussed in more detail in the entry [► Structured Singular Value and Applications: Analyzing the Effect of Linear Time-Invariant Uncertainty in Linear Systems](#).

Using the Nyquist stability criterion, the (G, Δ) interconnection is stable for all $\Delta \in \mathbf{\Delta}$, with $\bar{\sigma}(\Delta) < \beta$ if and only if G is stable, and

$$\det(I - G(j\omega)\Delta) \neq 0$$

for all $\Delta \in \mathbf{\Delta}$ with $\bar{\sigma}(\Delta) < \beta$ and all $\omega \in \mathbf{R}$ including $\omega = \infty$. The importance of the nonva-

nishing determinant condition warrants a definition of its own, the *structured singular value*. For a matrix $M \in \mathbb{C}^{n \times m}$, and Δ as given, define

$$\mu_{\Delta}(M) := \frac{1}{\min \{ \bar{\sigma}(\Delta) : \Delta \in \mathbf{\Delta}, \det(I - M\Delta) = 0 \}}$$

unless no $\Delta \in \mathbf{\Delta}$ makes $(I - M\Delta)$ singular, then $\mu_{\Delta}(M) := 0$. In this parlance, the (G, Δ) interconnection is stable for all $\Delta \in \mathbf{\Delta}$, with $\bar{\sigma}(\Delta) < \beta$ if and only if

$$\mu_{\Delta}(G(j\omega)) \leq \frac{1}{\beta}$$

for all $\omega \in \mathbf{R}$ including $\omega = \infty$.

In summary, the structured singular value approach employs a Nyquist-based argument, resulting in a nonvanishing determinant condition, which must hold over all frequency and all possible frequency-response values of the uncertain elements. However, checking the nonvanishing determinant is difficult, and sufficient conditions, in the form of semidefinite programs (Doyle 1982; Fan et al. 1991) to ensure this are derived. This results in semidefinite feasibility problems which must hold at all frequencies. It is common to verify these only on a finite grid of frequencies, which is equivalent to ensuring that the closed-loop poles cannot migrate across the stability boundary at these frequencies. Semidefinite programs can be defined which carve out intervals around these fixed frequencies to completely guarantee stability.

Robust Synthesis

Synthesis refers to the mathematical design of the control law. The nominal synthesis problem (with no uncertainty) is formulated using the generic feedback structure shown in Fig. 2. The various signals in the diagram are the control inputs u , measurements y , exogenous disturbances d , and regulated variables e . P is a generalized plant that contains all information required to specify the synthesis problem. This includes the dynamics of the actual plant being controlled as well as any frequency domain weights that are used to

Robust Synthesis and Robustness Analysis Techniques and Tools, Fig. 2 Feedback interconnection for H_2 , H_∞ , and $\mathcal{L}_1$ optimal control

specify the performance objective. The objective of an optimal control problem is to synthesize a controller K that minimizes the closed-loop (e.g., H_2 , H_∞ , $\mathcal{L}_1$) norm from disturbances (d) to regulated variables (e), i.e., solve

$$\min_{\text{allowable } K} \|F_L(P, K)\|$$

where $F_L(P, K)$ denotes the system obtained by closing the controller K around the lower loop of P . The H_2 , H_∞ , and $\mathcal{L}_1$ optimal control problems refer to the choice of the specific norm $\|F_L(P, K)\|$ used to specify the performance. A generalization of the H_∞ performance objective is simply to require that the closed-loop map from $d \rightarrow e$ satisfy an IQC defined by a given multiplier Π , called the performance multiplier, Apkarian and Noll (2006). The H_2 , H_∞ and $\mathcal{L}_1$ optimal control problems formulated as in Fig. 2 only involve signal uncertainty. In other words, these design problems do not explicitly account for the effects of model uncertainty.

Robust synthesis refers to control design that explicitly accounts for model uncertainty. It is usually formulated as a worst-case optimization, where the controller is chosen to minimize the worst-case effect of the signal and model uncertainty, loosely

$$\min_{\text{allowable } K} \max_{\text{allowable } d, \Delta} \|T(d, \Delta, K)\|$$

where d is a set of exogenous disturbances and Δ corresponds to the model uncertainty set. T represents the closed-loop relationship between

Robust Synthesis and Robustness Analysis Techniques and Tools, Fig. 3 Feedback interconnection for μ synthesis

d , Δ and the controller K . μ -synthesis is a specific technique developed to synthesize control algorithms which achieve robust performance, i.e., performance in the presence of signal and model uncertainty. The objective of μ -synthesis is to minimize over all stabilizing controllers K , the peak value of $\mu_{\Delta}(F_L(P, K))$ of the closed-loop transfer function defined by the interconnection in Fig. 3. P is the generalized plant model. The Δ block is the uncertain element from the set $\mathbf{\Delta}$, which parameterizes all of the assumed model uncertainty in the problem. The μ -synthesis optimization has high computational complexity (so-called NP-hard problem), though practical algorithms and software have been developed to design controllers using this control technique (Balas et al. 2013). Alternative robust synthesis approaches exist and often involve nonlinear optimization algorithms (Apkarian and Noll 2006). Drastic simplification regarding the models and uncertainty can be made resulting in problems that can be solved using LMI and semidefinite programming techniques (Boyd and Barrat 1991; Boyd et al. 1994).

Computational Tools

The MATLAB Robust Control Toolbox is a commercially available software product that

is part of the Mathworks control product line. It is tightly integrated with Control System Toolbox and Simulink products (Balas et al. 2013). The Robust Control Toolbox includes tools to analyze and design multi-input, multi-output control systems with uncertain elements. The primary building blocks, called uncertain elements or atoms, are uncertain real parameters and uncertain linear, time-invariant objects. These can be used to create coarse and simple or detailed and complex descriptions of model uncertainty. The uncertain object data structure eliminates the need to generate models of uncertainty and control analysis and design problem formulations, thereby allowing the practicing engineer to apply advanced robust control theory to their applications. Functions are available to analyze the robust stability, robust performance, and worst-case performance of uncertain multivariable system models using the structured singular value, μ . The Robust Control Toolbox also includes multivariable control synthesis tools to compute controllers that optimize worst-case performance and identify worst-case parameter values.

The IQC-Beta Toolbox is a publicly available robust analysis toolbox based on the IQC framework (Jönsson et al. 2004). A wide range of robust stability and performance analysis tests are available for uncertain, nonlinear, and time-varying systems. IQC-Beta is written in MATLAB and works seamlessly with the Control System Toolbox objects and basic interconnection functions. The Users manual nicely complements the literature on IQCs. The Computer Aided Control System Design package in Scilab, an open source numerical computation software, includes functionality for robustness analysis and the synthesis of robust control algorithms for multivariable systems (<http://www.scilab.org/>).

Conclusions

Robust control analysis and synthesis software tools are widely available and have been extensively used by industry since the late 1980s. The availability of software tools for robustness

analysis and synthesis played a major role in their wide and ubiquitous adoption in industry. They have been successfully applied to a variety of applications including aircraft flight control, launch vehicles, satellites, compact disk players, disk drives, backhoe excavators, nuclear power plants, helicopters, thin film extrusion, gas- and diesel-powered engines, missile autopilots, heating and ventilation systems, process control, and active suspension systems.

Magdeburg, Germany

²Institute for Systems Theory and Automatic
Control, University of Stuttgart, Stuttgart,
Germany

Abstract

Robustness analysis is the process of checking whether a system's function is maintained despite perturbations. Robustness analysis of biological models is typically applied to differential equation models of biochemical reaction networks. While robustness is primarily a yes-or-no question, for many applications in biological models, it is also desired to

compute a quantitative robustness measure. Such a measure is usually defined to be the maximum size of perturbations that the system can still tolerate. In addition, it is often of interest to specifically compute fragile perturbations, i.e., perturbations for which the system loses its function.

Keywords

Biochemical reaction networks · Fragile perturbations · Parametric uncertainty · Robustness measure · Structural uncertainty

Introduction

In biological systems analysis, robustness is the property that a system maintains its function in the face of internal or external perturbations (Kitano 2007). For a robustness analysis, one therefore needs to specify the system to be analyzed, the function that should be maintained, and the perturbation class.

The models to which robustness analysis is applied are mostly differential equation models of biochemical reaction networks. They are generally written as

$$\dot{x} = Sv(x), \quad (1)$$

where $x \in \mathbb{R}^n$ is the vector of intracellular concentrations; $S \in \mathbb{R}^{n \times m}$ is the stoichiometric matrix, containing the information how the individual network components participate in the reactions; and $v(x) \in \mathbb{R}^m$ is the reaction rate vector, in most cases a nonlinear function of the concentrations x .

The biological functions that are being studied by robustness analysis are very broad, pertaining to the wide range of biological functions implemented by biochemical reaction networks. Specific problems being considered are:

1. The occurrence of qualitative dynamical patterns such as sustained oscillations or multistability, where the system converges to one of multiple stable steady states depending on

initial conditions or external stimuli (Ma and Iglesias 2002; Eissing et al. 2005).

2. The steady-state concentration value for a subset of the biochemical network's components (Shinar and Feinberg 2010; Steuer et al. 2011).
3. Quantitative measures derived from the network's dynamics, for example, the period of sustained oscillations (Stelling et al. 2004).

For the perturbation classes, two approaches can be distinguished. In parametric robustness analysis, a parametrized biological model is given, and the perturbation consists in varying the values of the parameters away from their nominal value. In structural robustness analysis, perturbations to the interaction structure of the network or the functional form of the reaction rate functions $v(x)$ are considered. Robustness analysis with these perturbation classes is presented in more detail below.

The perturbation class is also relevant for two applications of robustness analysis which go beyond simply deciding whether a system is robust or not. First, it is often of interest to get a better quantification of robustness than a binary decision. Then, it is common to define a robustness measure, which usually quantifies how large perturbations can be without affecting the system's function (Morohashi et al. 2002; Ma and Iglesias 2002). Such a measure requires an appropriate definition of the perturbation size. With parametric perturbations, norms in parameter space are often useful (Ma and Iglesias 2002; Waldherr and Allgöwer 2011). With structural perturbations, the proximity of interaction functions in function space (Breindl et al. 2011) or the number of changes in the interaction structure can be evaluated.

Second, one often desires to compute specific non-robust perturbations, i.e., perturbations within the given class for which the system loses the considered functionality. There is a close relation between non-robust perturbations and the robustness measure, in that the norm of the smallest non-robust perturbation is equal to the robustness measure. Yet, it is often easier to compute a robustness measure than a non-robust perturbation. Especially algorithms that give a

Robustness Analysis of Biological Models, Fig. 1
Illustration of key characteristics in robustness analysis

lower bound on the robustness measure will usually not provide a non-robust perturbation.

An illustration of the key characteristics in robustness analysis is shown in Fig. 1.

This also illustrates that any norm-based robustness measure depends on the nominal situation, where no perturbation is present.

When performing robustness analysis on a mathematical model of the considered system, the potential mismatch between model and system has to be kept in mind. By comparing the mathematical analysis results to experimental observations, robustness analysis methods are also useful for the validation or invalidation of biological network models (Bates and Cosentino 2011).

Robustness Analysis with Parametric Perturbations

Robustness analysis with parametric perturbations is applied to parametrized differential equation models of biochemical reaction networks, which are described by an equation of the form

$$\dot{x} = Sv(x, \mu), \quad (2)$$

where $\mu \in \mathbb{R}^p$ is a vector of parameters. Such parameters may, for example, represent the total expression level of proteins involved in the reaction network, where usually a large variability

due to the stochastic process of gene expression occurs.

This entry focuses on two specific system functionalities for robustness with respect to parametric perturbations, the qualitative dynamical behavior, and the steady-state level of a subset of the network's components. These are particularly relevant for biological models: the dynamical behavior often represents qualitative biological regulatory mechanisms, whereas the steady-state level of network components with a downstream regulatory effect is important for the stimulus-response relation of a biological network.

The Qualitative Dynamical Behavior

Considering the qualitative dynamical behavior, it is of interest to distinguish situations of a globally stable equilibrium point, multiple locally stable equilibrium points, or sustained oscillations due to a limit cycle or more complex attractors. Since changes in these dynamical patterns correspond to the occurrence of bifurcations in the model dynamics (2), this type of robustness analysis is closely related to bifurcation analysis. In the case of scalar, positive parameters μ , a corresponding robustness measure DOR has been defined by Ma and Iglesias (2002) as

$$DOR = 1 - \max \left\{ \frac{\check{\mu}}{\mu_0}, \frac{\mu_0}{\hat{\mu}}, 0 \right\}, \quad (3)$$

where $\check{\mu}$ and $\hat{\mu}$ are the closest bifurcation points smaller and larger than μ , respectively. The robustness measure DOR is between 0 and 1 and indicates how much the parameter can be varied before reaching a bifurcation: for any multiplicative perturbation of less than $(1 - DOR)^{-1}$, no bifurcation will occur. A generalization to multiparametric models has been proposed in Waldherr and Allgöwer (2011): their robustness measure ϱ is defined as

$$\varrho = \sup \{ \varrho \geq 1 \mid \text{no bifurcation occurs in the hyperrectangle } [\varrho^{-1}\mu_0, \varrho\mu_0] \}. \quad (4)$$

The measure ϱ directly gives the multiplicative parameter variation up to which no bifurcation occurs.

In general, the information required for a bifurcation-based robustness measure will only be available from a complete bifurcation analysis of the model. When restricting the types of bifurcations that are considered to bifurcations of equilibrium point, one can however check robustness by studying linear approximations at the system's equilibrium points. Since the reaction rates $v(x, \mu)$ are usually modeled as polynomial or rational functions, polynomial programming methods can be applied to compute a robustness measure (Waldherr and Allgöwer 2011) in this case.

The Steady-State Output Concentration

In biochemical network analysis, mostly linear outputs of the form

$$y = Cx, \quad (5)$$

with $C \in \mathbb{R}^{q \times n}$ are considered. A common special case is that the rows of C are a subset of the rows of the identity matrix in $\mathbb{R}^n$, i.e.,

$$C = (e_i^T)_{i \in \mathcal{I}_y}, \quad (6)$$

and $\mathcal{I}_y \subset \{1, 2, \dots, n\}$ is the index set defining the output concentrations.

A biochemical network has a robust steady-state output concentration, if the steady-state output $\bar{y}$ is independent of the parameters μ (Steuer et al. 2011). For a steady-state map $\bar{y} = h(\mu)$, this corresponds to the condition

$$h'(\mu) = 0. \quad (7)$$

For the special case of an output given by (6), a sufficient and necessary condition for steady-state output robustness has been discovered by Steuer et al. (2011). The condition amounts to checking that a vector P , which describes the perturbation of the reaction rates under parameter variations, is in a subspace $\mathcal{I} = \text{im } M + \ker S \text{diag}(\alpha)$ for any α in the kernel of S , where M is a matrix composed

of the normalized derivatives of the reaction rates with respect to the concentrations which do not appear in the output. A notable underlying assumption here is that the network's steady state does not undergo any local bifurcations within the considered parameter region, which directly relates back to the robustness analysis discussed in the previous section.

For the special case where parameters are the concentrations of conserved chemical species, a sufficient condition for steady-state output robustness has also been discovered by Shinar and Feinberg (2010). They propose the term *absolute concentration robustness* for this property. Here, the assumption that no local bifurcations occur within the considered parameter region is not required a priori but rather is also a consequence of the proposed condition.

Robustness Analysis with Structural Perturbations

Robustness analysis with parametric perturbations is based on the assumption that the reaction rate expressions are exact and that all perturbations are captured by parameter variations. This assumption can hardly be justified for many practical models, and an analysis with structural perturbations becomes necessary. Such analyses have discovered models which are very robust against parametric perturbations but non-robust against structural perturbations (Jacobsen and Cedersund 2008).

The biological functions for which rigorous results on structural robustness are available are again related to the nonoccurrence of bifurcations in the model. For the restriction to local bifurcations of equilibria, linear systems theory offers efficient analysis tools for structural robustness.

In a first step, a structural perturbation of the network's interaction graph was suggested (Jacobsen and Cedersund 2008). This approach considers the network's Jacobian

$$A = S \frac{\partial v}{\partial x}(\bar{x}) \quad (8)$$

evaluated at a steady state $\bar{x}$. The Jacobian is then perturbed to

$$\tilde{A} = \text{diag } A + (A - \text{diag } A)(I + \Delta), \quad (9)$$

where $\text{diag } A$ is the diagonal of A and Δ is a perturbation matrix, containing uncertain time-invariant linear systems as elements.

As an alternative approach, Waldherr et al. (2009) have suggested a structural perturbation of the reaction rate expressions. Thereby, the network's Jacobian is perturbed to

$$\tilde{A} = S \left(\frac{\partial v}{\partial x}(\bar{x}) + \Delta \right). \quad (10)$$

In the case of real Δ , this perturbation simply corresponds to a change in the reaction rate slopes at steady state.

With both approaches, robustness analysis with structured singular values can be applied to test for changes in the local dynamics at the considered equilibrium point. This allows to evaluate a model's robustness against this type of structural perturbations and also yields non-robust perturbations.

Summary and Future Directions

Robustness analysis of biological models is well established in biological network theory. Mathematical methods rooted in systems and control are particularly beneficial for approaching this task.

While this entry focuses on models of biochemical reaction networks given by differential equations, the robustness analysis problem has also been studied in other model frameworks, for example, discrete dynamical models (Chaves et al. 2006). Yet, beyond simulation-based studies, robustness analysis is still an open problem in many practically relevant biological model classes. This concerns, for example, stochastic models or models on the cell population level.

In a similar manner, it will be important to extend the perturbation classes that are being considered and to include, for example, time-varying or other perturbations that are relevant for biological models. Concerning the biological function, most robustness analysis methods focus on the steady-state behavior. In the future, it

will be of interest to also take, for example, the transient dynamics into account.

In linear systems theory, the concept of robust performance is well established. While efforts have been made to transfer that concept to biochemical networks (Doyle and Stelling 2005), it remains difficult to quantify performance of such networks, thus impeding the development of stringent robustness analysis tools. One of the reasons for this difficulty is certainly that biological performance is more naturally defined in the time domain than in the frequency domain, which narrows the conclusions that could be drawn from a direct application of classical robust performance analysis methods.

Robustness Issues in Quantum Control

Ian R. Petersen

Research School of Electrical, Energy and Materials Engineering, Australian National University, Canberra, ACT, Australia

Abstract

Robust quantum control theory is concerned with the design of controllers for quantum

systems taking into account uncertainty in the model of the system. The robust open-loop control of quantum systems is discussed in this article. Also discussed is the robust stability analysis problem for quantum systems and two forms of quantum small gain theorem are presented. In addition, the article discusses the design of robust quantum feedback control systems.

Keywords

Quantum control · Robustness · Robust stability · Minimax control · Ensemble controllability · H^∞ control

Introduction

The control of systems whose dynamics are governed by the laws of quantum mechanics is the subject of quantum control theory. As in the case of classical control theory, the models used in quantum control are often subject to uncertainties. This motivates the study of robust quantum control, in which the quantum systems to be controlled are modelled as uncertain quantum systems; e.g., see Mabuchi and Khaneja (2005). A related problem, is the problem of robust estimation and filtering for uncertain quantum systems; e.g., see Yamamoto and Bouten (2009), Petersen (2017), and Xiang et al. (2017a, b). The issue of robust stability is particularly important in the case of quantum feedback control since, in this case, there is always the possibility of instability. An important area of quantum control theory is open-loop quantum control. Since uncertainties arise in the quantum system models being considered, the robustness of open-loop quantum control systems is also important; e.g., see Li and Khaneja (2009), Rabitz (2002), Owrutsky and Khaneja (2012).

This article surveys some of the important research results on robust quantum control which have arisen in various application areas. These include some recent results on robust open-loop control of quantum systems; see Zhang and Rabitz (1994). Also considered are some recent

robust stability analysis results for uncertain quantum systems, which amount to quantum versions of the classical small gain theorem; see Petersen et al. (2012). Finally, the article looks at robust quantum feedback controller design; see James et al. (2008) and Dong et al. (2009).

Robust Open-Loop Control of Quantum Systems

In the robust open-loop control of quantum systems, the quantum system is modeled in the Schrödinger picture. The models can be given either in terms of the Schrödinger equation for the system state $|\psi(t)\rangle$:

$$i \frac{\partial}{\partial t} |\psi(t)\rangle = \left[H_0 + \sum_{k=1}^m u_k(t) H_k \right] |\psi(t)\rangle \quad (1)$$

or the master equation for the system density operator ρ :

$$\dot{\rho}(t) = -i \left[\left(H_0 + \sum_{k=1}^m u_k(t) H_k \right), \rho(t) \right] \quad (2)$$

e.g., see Nurdin and Yamamoto (2017). In these equations, H_0 is the free Hamiltonian of the system and H_k are corresponding control Hamiltonians. Also, $i = \sqrt{-1}$ and m is the number of control inputs. In the robust open-loop control of quantum systems, these quantities are assumed to be uncertain, and the control law $u_k(t)$ is to be designed to guarantee an adequate level of performance for all possible values of the uncertainties. Here, performance is measured in terms of the fidelity between the actual final state or density matrix of the system and the desired final state or density matrix; e.g., see Nielsen and Chuang (2000).

In the minimax optimal control approach to robust open-loop control of quantum systems, the uncertainties in the Hamiltonian are represented in terms of a vector quantity w which is subject to constraints. Then, the robust control problem

is the minimax optimal control problem

$$\min_u \max_w J(u, w)$$

where $J(u, w)$ is a suitable cost function and the problem is subject to the constraints defined by the system dynamics (1) and the constraints on the uncertainty w ; see Zhang and Rabitz (1994). Some standard numerical procedures have been proposed to solve this minimax optimal control problem with applications in chemical physics; see Zhang and Rabitz (1994).

Related to the robust open-loop control of quantum systems is the control of inhomogeneous quantum ensembles. In this problem, the same control signal $u_k(t)$ is applied to a large number of quantum particles in an ensemble. Also, the Hamiltonians corresponding to individual particles may have different parameter values, and so this problem is equivalent to a robust open-loop quantum control problem; e.g., see Li and Khaneja (2006). In studying this problem, the issue of controllability has been considered (see e.g., Li and Khaneja 2009) as in the standard open-loop quantum control problem. Also, numerical methods have been proposed for constructing an optimal control law for inhomogeneous ensembles; e.g., see Ruths and Li (2012); Owrutsky and Khaneja (2012). This approach has arisen in applications to chemical physics.

Robustness Analysis for Uncertain Quantum Systems

The problem of robust stability analysis for uncertain quantum systems was considered in the paper D'Helon and James (2006) which was concerned with the feedback interconnection of two quantum optical systems as shown in Fig. 1. In this interconnection, each of the quantum systems is a linear quantum optical system described in the Heisenberg picture by linear quantum stochastic differential equations (QSDEs) of the form

$$dx(t) = Ax(t)dt + Bdu(t);$$

$$dy(t) = Cx(t)dt + Ddu(t); \quad (3)$$

see James et al. (2008) for more details on this class of quantum system models. Here, $x(t)$ is a vector system variables which are operators on the underlying Hilbert space of the system. Also, the input and output fields are decomposed as $du(t) = \beta_u(t)dt + d\tilde{u}(t)$ and $dy(t) = \beta_y(t)dt + d\tilde{y}(t)$ where $\beta_u(t)$, $\beta_y(t)$ denote the signal parts of the quantities $du(t)$, $dy(t)$ respectively. Furthermore, $d\tilde{u}(t)$, $d\tilde{y}(t)$ denote the noise parts of the quantities $du(t)$, $dy(t)$ respectively; e.g., see James et al. (2008). Such a system is stable and has a finite gain $g > 0$ if there exist constants $\mu > 0$ and $\lambda > 0$ such that

$$\int_0^t \langle \|\beta_y(\tau)\|^2 \rangle d\tau \leq \mu + \lambda t \\ + \int_0^t \langle \|\beta_u(\tau)\|^2 \rangle d\tau \quad \forall t > 0;$$

e.g., see D'Helon and James (2006) and James and Gough (2010). Here $\langle \cdot \rangle$ denotes quantum expectation.

The two quantum optical systems shown in Fig. 1 are interconnected via beam splitters which are described by equations

$$\begin{aligned} u_1 &= \epsilon_1 w_1 - \sqrt{1 - \epsilon_1^2} y_2; \\ z_1 &= \sqrt{1 - \epsilon_1^2} w_1 + \epsilon_1 y_2; \\ u_2 &= \epsilon_2 w_2 - \sqrt{1 - \epsilon_2^2} y_1; \\ z_2 &= \sqrt{1 - \epsilon_2^2} w_2 + \epsilon_2 y_1 \end{aligned}$$

where $\epsilon_1 \in (0, 1)$ and $\epsilon_2 \in (0, 1)$ are given constants. The quantum small gain theorem established in D'Helon and James (2006) shows that if both of the quantum systems in Fig. 1 are stable and have finite gains $g_1 > 0$ and $g_2 > 0$, respectively, such that $\sqrt{1 - \epsilon_1^2} \sqrt{1 - \epsilon_2^2} g_1 g_2 < 1$, then the feedback interconnected system will also be stable and have a finite gain. This result can be thought of as a stability robustness result if the first quantum system is regarded as the nominal quantum system and the second quantum system

is regarded as being the uncertain part of the system subject to the given finite gain constraint.

An alternative approach to the robust stability analysis of uncertain quantum systems considers an uncertain quantum system described using the (S, L, H) description (see Gough and James 2009 for more details on this class of quantum systems). Here, the system Hamiltonian is described in terms of vectors of annihilation and creation operators a and $a^\#$, respectively, as

$$H = \frac{1}{2} \begin{bmatrix} a^\dagger & a^T \end{bmatrix} M \begin{bmatrix} a \\ a^\# \end{bmatrix} + \frac{1}{2} \tilde{\zeta}^\dagger \Delta \tilde{\zeta}$$

where $a^\dagger = (a^\#)^T$, M is a known complex Hermitian matrix describing the nominal Hamiltonian, and Δ is a complex Hermitian uncertainty matrix subject to the norm bound $\|\Delta\| \leq \frac{2}{\gamma}$,

and $\tilde{\zeta} = E \begin{bmatrix} a \\ a^\# \end{bmatrix}$, where E is a known complex matrix describing the uncertainty structure. Here $\gamma > 0$ is a given constant. Furthermore, it is assumed that the scattering matrix $S = I$ and the coupling operator vector L is such that $\begin{bmatrix} L \\ L^\# \end{bmatrix} = N \begin{bmatrix} a \\ a^\# \end{bmatrix}$ where N is a known complex matrix. This uncertain quantum system is robustly mean square stable if the H^∞ norm bound condition

$$\left\| E \left(sI + iJM + \frac{1}{2} JN^\dagger JN \right)^{-1} J E^\dagger \right\|_\infty < \frac{\gamma}{2}$$

is satisfied where $J = \begin{bmatrix} I & 0 \\ 0 & -I \end{bmatrix}$; see Petersen et al. (2012).

Robust Feedback Control of Quantum Systems

Schrödinger Picture Approaches to Robust Measurement-Based Quantum Feedback Control

A number of results have appeared which use Schrödinger picture models in robust measurement based quantum feedback control. These

Robustness Issues in Quantum Control, Fig. 1

Feedback interconnection of two quantum optical systems

results are based on uncertain quantum system models of the form (1) or (2) and extend the results mentioned above by allowing for measurements of the quantum system in order to achieve improved robustness against uncertainties in the system Hamiltonian. For example, consider a quantum system of the form (1) with uncertainties in the system Hamiltonian. Then a measurement feedback robust control scheme can be constructed which involves periodic projective measurements on the system. In a projective measurement of the quantum system (1), the state $|\psi(t)\rangle$ collapses to an eigenstate of H_0 corresponding to the measurement outcome obtained. The sliding mode control algorithm uses open-loop time optimal control to steer the state of the system back to a specified eigenstate of the system whenever a measurement is obtained which does not correspond to this desired eigenstate; see Dong and Petersen (2009). This desired eigenstate is referred to as the sliding mode domain and the state of the system is guaranteed to stay within the sliding mode domain with a specified probability provided that the measurement sampling period in the proposed feedback control algorithm is chosen to be sufficiently fast; see Dong and Petersen (2009). In the case of two-level quantum systems, this sliding mode control approach is implemented using a Lyapunov method for open-loop quantum control to steer the system back to the sliding mode domain; see Dong and Petersen (2012). In all of these cases,

robustness is ensured by including uncertainty in the underlying quantum system models and then taking this into account in the design of the control laws and sampling period.

Another approach to the measurement-based robust quantum feedback control problem involves an extension of the robust open-loop control results considered in the section “[Robust Open-Loop Control of Quantum Systems](#).” In this approach, robust open-loop control results are extended to solve the problem of stabilization of an ensemble of quantum particles; see Beauchard et al. (2012).

Heisenberg Picture Approaches to Robust Quantum Feedback Control

Consider a quantum linear system modeled in the Heisenberg picture by quantum stochastic differential equations (QSDEs) as follows

$$\begin{aligned} dx(t) &= Ax(t)dt + Bd w(t); \\ dy(t) &= Cx(t)dt + Dd w(t); \end{aligned} \quad (4)$$

see Nurdin and Yamamoto (2017) for details on this class of quantum system models which arises in the area of quantum optics. In the robust quantum feedback control problem, the matrices A , B , C , D may be uncertain, and a feedback controller can be designed using the quantum H^∞ control approach to ensure that the resulting closed loop system is robustly stable; see James

et al. (2008). In the case of measurement-based feedback control, the controller is a classical system described by linear stochastic differential equations of the form

$$\begin{aligned} dx_K(t) &= A_K x_k(t)dt + B_K dy(t) \\ \beta_u(t)dt &= C_K x_k(t)dt; \end{aligned} \quad (5)$$

see Nurdin and Yamamoto (2017). In the case of coherent feedback control, the controller is another quantum linear system described by QSDEs of the form

$$\begin{aligned} dx_K(t) &= A_K x_k(t)dt + B_K dy(t) + \bar{B}_K d\bar{w}_K(t) \\ dy_K(t) &= C_K x_k(t)dt + \bar{D}_K d\bar{w}_K(t); \end{aligned} \quad (6)$$

see Nurdin and Yamamoto (2017).

In this approach to robust quantum feedback control, the uncertainty in the quantum system being controlled is represented by uncertainty in the matrix A as $A = \hat{A} + \bar{B}\Delta\bar{C}$ where Δ is a constant but unknown uncertain matrix satisfying the bound $\Delta^T \Delta \leq I$. The controller, which may be either a classical controller or a coherent controller, is designed using the quantum H^∞ approach. Then the resulting closed loop system will be robustly stable; see James et al. (2008). Similarly, in the case of uncertainty in the plant Hamiltonian matrix such as considered in the section “[Robustness Analysis for Uncertain Quantum Systems](#)” or uncertainty in the form of an uncertain subsystem connected optically to the plant in feedback, also as considered in the section “[Robustness Analysis for Uncertain Quantum Systems](#),” then the quantum H^∞ approach combined with the robust stability analysis results of the section “[Robustness Analysis for Uncertain Quantum Systems](#)” shows that the quantum H^∞ method can also be used to design robustly stabilizing controllers in these cases.

Summary and Future Directions

To date there have been only a few papers published in the general area of robust quantum control. The results which were considered in

this article covered open-loop and feedback quantum control problems along with stability robustness analysis problems. A common theme in the results which were considered is that they were based on uncertain quantum mechanical models. It is expected that future research in this area will intensify as the use of feedback control becomes more prevalent in areas of experimental quantum technology.

Abstract

Routing is an effective way to control traffic to optimize network-level objective. The effectiveness depends in part on complex traffic flow dynamics and driver preferences. We

provide an overview of the basics of routing design under such considerations and point to promising research directions.

Keywords

Traffic flow dynamics over network · Robustness · Routing under information constraint · Social optimality · User equilibrium

Introduction

We start with a simple setting, through which we also describe preliminaries. The directed graph structure of a transportation network is described by the tuple $\mathcal{G} = (\mathcal{V}, \mathcal{E}, c)$, where $\mathcal{V}$ is the set of nodes, $\mathcal{E}$ is the set of directed edges, and c is the set of edge-wise flow capacities. Two specific nodes $o \in \mathcal{V}$ and $d \in \mathcal{V}$ are, respectively, designated to be the origin and destination nodes. Without loss of generality, we let o (resp., d) have no incoming (resp., outgoing) edge and only one outgoing (resp., incoming) edge, say i_{in} (resp., i_{out}), with unbounded capacity $c_{i_{\text{in}}} = \infty$ (resp., $c_{i_{\text{out}}} = \infty$); see Fig. 1a for an illustration. $\mathcal{E}_v^+$ (resp., $\mathcal{E}_v^-$) denotes the set of edges outgoing from (resp., incoming to) node v . The head node of $i \in \mathcal{E}$ is denoted as τ_i . Each edge $i \in \mathcal{E}$ is associated with a flow variable $f_i \geq 0$. At times, it will be convenient to refer to the set $\hat{\mathcal{E}} := \mathcal{E} \setminus \{i_{\text{in}}, i_{\text{out}}\}$ of edges other than the ones associated with the origin and destination nodes.

Routing is an assignment of flow $\{f_i\}_{i \in \mathcal{E}}$ to edges of the transportation network subject to certain constraints. A simple form of such an assignment is solution to the following linear program:

$$\min_{f_i, i \in \mathcal{E}} \sum_{i \in \mathcal{E}} g_i f_i \quad (1a)$$

$$\sum_{i \in \mathcal{E}_v^-} f_i = \sum_{i \in \mathcal{E}_v^+} f_i, \quad v \in \mathcal{V} \setminus \{o, d\} \quad (1b)$$

$$f_i = \lambda, \quad i \in \{i_{\text{in}}, i_{\text{out}}\} \quad (1c)$$

$$0 \leq f_i \leq c_i, \quad i \in \mathcal{E} \quad (1d)$$

Routing in Transportation Networks, Fig. 1 Illustration of (a) transportation network topology; (b) demand and supply functions on a sample edge i

where $\{g_i\}_{i \in \mathcal{E}}$ are cost coefficients in (1a); (1b) represents flow conservation at nodes; (1c) captures the requirement that a constant rate of traffic $\lambda > 0$ needs to be routed from o to d ; and (1d) captures non-negativity and edge-wise capacity constraints on flow. A necessary and sufficient condition for (1) to admit a feasible solution is that λ is less than or equal to the minimum among capacities of all $o - d$ cuts in the networks. An $o - d$ cut is a subset of edges $\tilde{\mathcal{E}} \subset \mathcal{E}$, such that $o \in \tilde{\mathcal{E}}$ and $d \notin \tilde{\mathcal{E}}$. The capacity of cut $\tilde{\mathcal{E}}$ is the sum of capacities of all edges outgoing from $\tilde{\mathcal{E}}$.

The notion of *residual* capacity plays a key role in tight characterization of robustness in terms of loss in capacities under which routing is feasible. For instance, if the loss in capacities from c to $\tilde{c} \leq c$ is such that $\|c - \tilde{c}\|_1$ is no greater than the *network residual capacity*, then routing under (1) with new capacities $\tilde{c}$ is feasible. Network residual capacity is the difference between its min-cut capacity and λ .

The framework in (1) is for socially optimal routing in static setting (Cascetta 2009). Extensions to traffic flow dynamics are discussed in section “Routing Dynamical Traffic Flow over Network”, and extensions to settings which take into account driver preferences are discussed in section “Routing Under Driver Preferences”. The setup outlined in this section is for single-commodity flow, i.e., when there is no constraint on which destination node the flow needs to be routed to. The single origin-destination setting in (1) is the simplest such setting. Extension to multiple origins and destinations for single-commodity flow is straightforward. The

discussion in section “Fixed Routing” applies also to multi-commodity flow, but the discussion in section “Dynamic Routing” does not. Future directions and further reading are suggested in sections “Summary and Future Directions” and “Recommended Reading” respectively. Finally, unless stated otherwise, the network topology is assumed to be directed acyclic such that, for every $v \in \mathcal{V} \setminus \{o, d\}$, there exists a directed path from o to v and from v to d .

Routing Dynamical Traffic Flow over Network

The set of f satisfying (1b)–(1c) can be parameterized in terms of, not necessarily unique, routing matrix $R \in [0, 1]^{\mathcal{E} \times \mathcal{E}}$, i.e., a row stochastic matrix whose (i, j) -th entry R_{ij} specifies what fraction of flow from i gets routed to j . Naturally, $R_{ij} = 0$ if i is not incident to j . Formally, for every f satisfying (1b)–(1c), there exists R such that

$$R^T f + \lambda \mathbf{1}_{i_{in}} = f \quad (2)$$

and vice-versa, where $\mathbf{1}_{i_{in}}$ is a vector of size $|\mathcal{E}|$ whose i_{in} -th entry is one, and other entries are zero.

Traffic Flow Dynamics

Equation (2) can be regarded as corresponding to equilibrium of the following mass balance equations:

$$\dot{x}_i = \sum_{j \in \mathcal{E}} R_{ji} f_j(x) - f_i(x), \quad i \in \hat{\mathcal{E}} \quad (3)$$

where x_i denotes traffic density (The density is assumed to be uniform over an edge. We also assume, without loss of generality, that all the edges have unit length.) on link i and $f_i(x)$ (For brevity in notation, we use the same notation f to denote a specific flow vector as well as the function which maps density x to outflow. The specific usage should be clear from the context.) is interpreted as the *outflow* from link i with $f_{i_{in}}(x) \equiv \lambda$. We now describe a few settings for dependence of f on x . A simple model is where, for $i \in \hat{\mathcal{E}}$, $f_i(x) \equiv d_i(x_i)$, where the d_i 's are continuously differentiable, strictly increasing and strictly concave such that $d_i(x_i) = 0$ and upper bounded by c_i . The latter models the capacity constraint in (1d). An example is:

$$d_i(x_i) = c_i (1 - e^{-\beta x_i}), \quad \beta > 0, \quad i \in \hat{\mathcal{E}} \quad (4)$$

A generalization is where

$$f_i(x) = \gamma_i(x) d_i(x_i), \quad \gamma_i(x) \in [0, 1] \quad (5)$$

In the *cell transmission model* (CTM) (Daganzo 1995) and its variants, $\gamma_i(x)$ captures the dependence of outflow on immediately downstream links, in the context of freeway networks, as follows. Equation (3) is augmented with:

$$\dot{x}_{i_{in}} = \lambda - f_{i_{in}}(x) \quad (6)$$

where, for CTM, $f_{i_{in}}(x)$ is as in (5) with finite $c_{i_{in}}$. The d_i 's, $i \in \hat{\mathcal{E}} \cup \{i_{in}\}$, are interpreted as *demand* functions, and each $i \in \hat{\mathcal{E}} \cup \{i_{out}\}$ is associated with a *supply* function $s_i(x_i)$. The s_i 's, $i \in \hat{\mathcal{E}}$, are continuously differentiable, strictly decreasing, and strictly concave, such that $s_i(0) > 0$ with $s_i(x_i^{\text{jam}}) = 0$ for some $x_i^{\text{jam}} > 0$ known as the *jam density* of i . See Fig. 1b for an illustration. By convention, $s_{i_{out}}(x) \equiv \infty$. Under a variant of CTM:

$$\gamma_i(x) = \sup \left\{ \theta \in [0, 1] : \max_{j \in \mathcal{E}} \left(\theta \cdot \sum_{k \in \mathcal{E}} R_{kj} d_k(x_k) - s_j(x_j) \right) \leq 0 \right\} \quad (7)$$

An alternative to (5) commonly used to study the average traffic flow dynamics over signalized networks is:

$$f_i(x_i) = \begin{cases} \gamma_i(x) c_i, & x_i > 0 \\ \min\{\gamma_i(x) c_i, \sum_j R_{ji} f_j(x)\}, & x_i = 0 \end{cases}, \quad i \in \hat{\mathcal{E}}, \quad \sum_{i \in \mathcal{E}_v^-} \gamma_i(x) \leq 1, \quad v \in \mathcal{V} \quad (8)$$

where γ_i 's are given by a specific traffic signal control policy.

A generalization of (3) is to dynamic routing which can be either open-loop as $R(t)$ or in feedback form:

$$\dot{x}_i = \sum_{j \in \mathcal{E}} R_{ji}(x) f_j(x) - f_i(x), \quad i \in \hat{\mathcal{E}} \quad (9)$$

Routing and outflow can be combined into inter-edge flow $z_{ij}(x) := f_i(x) R_{ij}(x)$ to further gener-

alize (9) as:

$$\dot{x}_i = \sum_{j \in \mathcal{E}} z_{ji}(x) - \sum_{j \in \mathcal{E}} z_{ij}(x), \quad i \in \hat{\mathcal{E}} \quad (10)$$

where $\sum_{j \in \mathcal{E}} z_{ij}(x) = f_i(x) \sum_{j \in \mathcal{E}} R_{ij}(x) = f_i(x)$. Equation (10) is augmented either with $\sum_{j \in \mathcal{E}} z_{i_{in}j}(x) = f_{i_{in}}(x) \equiv \lambda$ or with (6).

Fixed Routing

A necessary condition for the existence of an equilibrium x^* for (3) with $f(x)$ in (5) and

$\gamma_i(x) = 1$ for all $i \in \hat{\mathcal{E}}$ is that there exists $f^* \in [0, c]$ such that $f_i^* = \sum_{j \in \mathcal{E}} R_{ji} f_j^*$ for all $i \in \hat{\mathcal{E}}$ and $f_i^* = \lambda$ for $i \in \{i_{\text{in}}, i_{\text{out}}\}$. Under the same condition, existence of a global asymptotically stable x^* can be established. Additionally, robustness to loss in capacity, within the same formalism as in section “Introduction”, is equal to the minimum edge residual capacity, i.e., $\min_{i \in \hat{\mathcal{E}}} (c_i - f_i^*)$.

A necessary condition for the existence of equilibrium for (3), (8) is the existence of f^* satisfying the necessary condition above for (3), (5) with $\gamma_i(x) = 1$ for all $i \in \hat{\mathcal{E}}$, and additionally, $\sum_{i \in \mathcal{E}_v^-} \frac{f_i^*}{c_i} \leq 1$ for all $v \in \mathcal{V}$. If the necessary condition is satisfied, then under the centralized open-loop controller $\gamma_i(x) \equiv f_i^*/c_i$, $i \in \mathcal{E}$, every $x > \mathbf{0}$ is an equilibrium. It is shown in Savla et al. (2013) that, if the necessary condition is satisfied, then, under the decentralized controller $\gamma_i(x) = \frac{x_i}{\sum_{j \in \mathcal{E}_i^+} x_j + \kappa}$, $\kappa > 0$, there exists a unique $x^* > \mathbf{0}$ whose basin of attraction is $\mathbf{R}_{>0}^{\mathcal{E}}$. Extension of this result to cyclic graph topology, as would be relevant, e.g., for multi-commodity flow, is possible by establishing $\sum_{i \in \hat{\mathcal{E}}} x_i \log(\gamma_i(x) \frac{c_i}{f_i^*})$ as Lyapunov function, the inspiration for which comes from the literature on stochastic networks, e.g., see Massoulié (2007). Note that the decentralized controller gives the same stability guarantee as the centralized open-loop controller without requiring information about (even local) λ , R or c required to compute f^* . The literature on back pressure controllers, e.g., see Tassiulas and Ephremides (1992), suggests that one can get the same stability guarantee by establishing $\sum_{i \in \mathcal{E}} x_i^2$ as Lyapunov function. Such tight stability guarantees translate into tight guarantees on robustness to loss in capacities. That is, for a loss in capacity, if there exists a centralized controller under which $x(t)$ remains bounded, then it does so also under the above decentralized controllers, hence no loss in robustness under decentralized control.

A more accurate model to capture the alternating red and green states of traffic signal for a given road in signalized networks is (3) with $f_i(x) = c_i(t)$ if $x_i > 0$ and equal to $\min\{c_i(t), \sum_j R_{ji} f_j(x)\}$ if $x_i = 0$, where $c_i(t)$

is an exogenous periodic capacity function. In this setting, Muralidharan et al. (2015) provides tight conditions for the existence of a unique periodic $x^*(t)$ to which every trajectory converges to, and (Hosseini and Savla 2017) provides a procedure to compute $x^*(t)$. Extension to feedback-based periodic $c_i(t)$ is outstanding. Finally, comprehensive stability and robustness analysis of (9), (5) under (7) is still ongoing, with partial results reported in Lovisari et al. (2014).

Dynamic Routing

A necessary condition for the existence of an equilibrium x^* for (9) with $f(x)$ in (5) and $\gamma_i(x) = 1$ for all $i \in \hat{\mathcal{E}}$ is that λ is not greater than the min-cut capacity. Under this condition, existence and global asymptotic stability of x^* is shown in Como et al. (2013a, b) under a class of decentralized routing $R_{ij}(x, x^*) \equiv R_{ij}(\{x_\ell, x_\ell^* : \ell \in \mathcal{E}_{t_i}^+\})$, referred to as *monotone routing*, parameterized by x^* . This class is defined by two properties: (I) $R_{ij}(\{x_\ell^*, x_\ell^* : \ell \in \mathcal{E}_{t_i}^+\}) = \frac{f_j(x_j^*)}{\sum_{k \in \mathcal{E}_{t_i}^+} f_k(x_k^*)}$ for all $j \in \mathcal{E}_{t_i}^+$, $i \in \mathcal{E}$ and (II) $\frac{\partial}{\partial x_k} R_{ij}(\{x_\ell, x_\ell^* : \ell \in \mathcal{E}_{t_i}^+\}) \geq 0$ for all x , $\{j, k\} \in \mathcal{E}_{t_i}^+$, $j \neq k$, $i \in \mathcal{E}$. An example of monotone routing is:

$$R_{ij}(\{x_\ell, x_\ell^* : \ell \in \mathcal{E}_{t_i}^+\}) = \frac{f_j(x_j^*) e^{-\eta(x_j - x_j^*)}}{\sum_{k \in \mathcal{E}_{t_i}^+} f_k(x_k^*) e^{-\eta(x_k - x_k^*)}},$$

$$\eta > 0, \quad \forall i \in \mathcal{E} \setminus \{i_{\text{out}}\} \quad (11)$$

Monotone routing also possesses the following sharp robustness property. For every loss in capacity from c to $\tilde{c} \leq c$ such that $\|c - \tilde{c}\|_1$ is no greater than the minimum, over $v \in \mathcal{V} \setminus \{d\}$, *node residual capacity* w.r.t. $f(x^*)$, there exists a new globally asymptotically stable equilibrium under monotone routing. Residual capacity of v w.r.t. $f(x^*)$ is $\sum_{i \in \mathcal{E}_v^+} (c_i - f_i(x_i^*))$. On the other hand, if the loss in capacity on edges in $\mathcal{E}_v^+$ corresponding to v with minimum node residual capacity exceeds their respective residual capacities w.r.t. $f(x^*)$, then $\|x(t)\|$ grows unbounded under every decentralized, i.e., not necessarily monotone, routing. The minimum node residual capacity is less than or equal to the network residual

capacity, which, from section “[Introduction](#)”, is the analogous robustness measure in the static and centralized setting. The gap could be substantial for large networks, suggesting loss in robustness due to loss of information when routing. This gap can be overcome either by providing more information (Como et al. 2013c) or by augmenting routing with an extra control action (Como et al. 2015).

One way to provide more information is by letting the parameter x^* adapt to global information. In Como et al. (2013c), x^* is interpreted as *anticipated* traffic density by drivers who use it as a proxy for global state of the network when making local routing decisions according to monotone routing. x^* is updated by drivers using global information according to a best response dynamics over a slower time scale. If the time scale separation is sufficiently large and if λ is not greater than the min-cut capacity, then it is shown in Como et al. (2013c) that the Wardrop equilibrium (see section “[Routing Under Driver Preferences](#)”) is globally stable. An implication of this is that multiscale routing has the same robustness performance as centralized routing has for the static setting, as described in section “[Introduction](#)”.

In Como et al. (2015), it is shown how loss in robustness can also be recovered by augmenting decentralized routing with decentralized flow control action, as in (10). Specifically, it is shown that, under a monotone decentralized $z_{ij}(x) \equiv z_{ij}(\{x_\ell : \ell \in \{i\} \cup \mathcal{E}_i^+\})$, if λ is no greater than the min-cut capacity, then (10) admits a globally asymptotically stable equilibrium, which then also implies the same robustness performance as centralized routing for the static setting in section “[Introduction](#)”. This result is true even if the graph topology is cyclic, to allow multiple origins and destinations within single commodity flow setting. The monotonicity conditions are, for all $i \in \mathcal{E}$: $\frac{\partial}{\partial x_k} z_{ij}(\{x_\ell : \ell \in \{i\} \cup \mathcal{E}_i^+\}) \geq 0$ for all $k \in \{i\} \cup \mathcal{E}_i^+ \setminus \{j\}$ and $\frac{\partial}{\partial x_k} \sum_{j \in \mathcal{E}_i^+} z_{ij}(\{x_\ell : \ell \in \{i\} \cup \mathcal{E}_i^+\}) \leq 0$ for all $k \in \mathcal{E}_i^+$. An example is $z_{ij}(x) = \gamma_i(x) d_i(x_i) R_{ij}(x)$ with $\gamma_i(x) = \frac{\sum_{k \in \mathcal{E}_i^+} e^{-\eta x_k}}{\sum_{k \in \{i\} \cup \mathcal{E}_i^+} e^{-\eta x_k}}$, $\eta > 0$, $d_i(x_i)$ as in (4) and $R_{ij}(x) = \frac{e^{-\eta x_j}}{\sum_{k \in \mathcal{E}_i^+} e^{-\eta x_k}}$.

Rigorous stability and robustness analysis of (9), (6), (5) under (7) is outstanding. However, optimal solution to the following dynamic version of (1), also known as *dynamic traffic assignment*, has been derived in Como et al. (2016); Jafari and Savla (2019): $\min_{(\alpha(t), R(t)): t \in [0, T]} \int_0^T \psi(x(s), f(s)) ds$ s.t. (9), (6), (5), (7) with $d_i(x_i)$ replaced by $\alpha_i d_i(x_i)$, convex ψ , given initial condition $x(0)$ and control horizon T . $\alpha_i \in [0, 1]$ is interpreted as variable speed limit control on $i \in \hat{\mathcal{E}}$ and as ramp metering control on i_{in} . The solution is synthesized in two steps. First, an optimal solution is obtained for the following convex relaxation of (7): $\min_{(x(t), z(t)): t \in [0, T]} \int_0^T \psi(x(s), f(s)) ds$ s.t. (10), (6), initial condition $x(0)$, $\sum_j z_{ij}(t) \leq d_i(x_i(t))$ for all $i \in \hat{\mathcal{E}} \cup \{i_{in}\}$ and $t \in [0, T]$, and $\sum_j z_{ji}(t) \leq s_i(x_i(t))$ for all $i \in \hat{\mathcal{E}} \cup \{i_{out}\}$ and $t \in [0, T]$. In the second step, setting $R_{ij}^*(t) = \frac{z_{ij}^*(t)}{\sum_{k \in \mathcal{E}_i^+} z_{ik}^*(t)}$ and $\alpha_i^*(t) = \frac{\sum_{j \in \mathcal{E}_i^+} z_{ij}^*(t)}{d_i(x_i^*(t))}$ implies that $\{(x_i^*(t), f_i^*(t) = \alpha_i^*(t) d_i(x_i^*(t)) : i \in \hat{\mathcal{E}} \cup \{i_{in}\})\}$ satisfies (7) with $\gamma_i(x^*(t)) = \alpha_i^*(t)$. This proves optimality of $(\alpha^*(t), R^*(t))$ for the original unrelaxed problem. If ψ is separable over the edges, then the first step can be executed efficiently using distributed iterative algorithms, e.g., as in Ba and Savla (2016). If ψ is linear, then, in discrete time setting, using multi-parametric programming technique, the optimal solution in the first step can be equivalently expressed in feedback form $z^*(x(t))$ which is piecewise affine. Additionally, Jafari and Savla (2019) provides the most general known sufficient condition on the network topology and coefficients in linear ψ under which the feedback structure admits a decentralized form. These then translate into corresponding feedback and decentralization forms for (α^*, R^*) in the second step.

Routing Under Driver Preferences

The routing policies presented in section “[Routing Dynamical Traffic Flow over Network](#)” can be regarded as minimizing social cost, whether that be the negative of robustness or others modeled by ψ . For instance, the monotone routing in

(11) can be regarded as the probability of a single driver choosing edge j among $\mathcal{E}_{\tau_i}^+$ under the multinomial logit model, if the cost, or disutility, associated with $j \in \mathcal{E}_{\tau_i}^+$ is $x_j - x_j^* - \log f_j(x_j^*)$. However, the cost actually assigned by drivers might be different. The routing outcome under such user-centric cost functions in the static setting is given by *user equilibrium*. A flow assignment is called user equilibrium if the cost of each path from o to d actually used, i.e., on which flow is positive, is equal and is less than or equal to the cost of a path not used. A natural candidate for user-centric cost function is travel time; the user equilibrium in this special case is also often referred to as *Wardrop equilibrium*.

User equilibrium flow, in general, does not minimize social cost. The disparity is often formalized through *price of anarchy*, e.g., see Nisan et al. (2007), defined as the ratio between the social cost of user equilibrium flow and the minimum possible under socially optimal routing. In case of multiple user equilibria, it is defined to be the largest ratio over all user equilibria. Edge-wise tolls are among the most widely studied mechanisms to reduce the price of anarchy, as follows. Since tolls affect the cost that a driver associates with a path, and therefore also the resulting user equilibrium flow, they can potentially be used to align user equilibrium flow with socially optimal flow. Indeed, let f^{opt} minimize $\sum_i f_i \cdot \text{TT}_i(f_i)$ subject to constraints in (1), where $\text{TT}_i(f_i)$ is flow-dependent travel time on edge $i \in \hat{\mathcal{E}}$. Let the user cost of a path be the sum of costs of edges on that path, and let the user cost for an edge i be the sum of $\text{TT}_i(f_i)$ and fixed toll τ_i . If, for every $i \in \hat{\mathcal{E}}$, $\tau_i = f_i^{\text{opt}} \cdot \text{TT}'_i(f_i^{\text{opt}})$, TT_i is continuous differentiable and strictly increasing, and $f_i \cdot \text{TT}_i(f_i)$ is convex, then f^{opt} is also a user equilibrium (Nisan et al. 2007). Here, TT'_i denotes the derivative of TT w.r.t. f_i . Optimal toll design in dynamical settings is outstanding in general.

Summary and Future Directions

Routing design for transportation networks has traditionally focused on centralized, static, or open-loop settings. Distributed feedback routing

under realistic traffic flow dynamics, preferably under output feedback that captures common sensing modes in traffic, is a fruitful direction to pursue. In this context, multi-commodity flow particularly remains largely unexplored and therefore presents great opportunities. While monetary mechanisms, such as tolls, have been studied extensively as means to align user- and system-level objectives, information design schemes are gaining interest in this context. However, it remains to integrate them properly with the transportation settings.

Recommended Reading

Extensive discussion on traffic assignment models and solution algorithms can be found in Patriksson (1994); Cascetta (2009). The majority of the stability analysis reported in section “[Routing Dynamical Traffic Flow over Network](#)” utilizes contraction theory, e.g., see Sontag (2010), by exploiting monotonicity of underlying dynamical systems (Hirsch and Smith 2006). Distributed routing under cascading failure dynamics is relatively unexplored; one specific setting is studied in Savla et al. (2014).

Run-to-Run Control in Semiconductor Manufacturing

James Moyne

Mechanical Engineering Department, University of Michigan, Ann Arbor, MI, USA

Abstract

Run-to-run (R2R) control is a form of adaptive model-based process control that can be tailored to environments where the process is discrete, dynamic, and highly unobservable; this is characteristic of processes in the semiconductor manufacturing industry. It generally has, at its roots, a rather straightforward approach to adaptive model-based control such as a first-order linear plant model with moving average weighting applied to adapt the (zeroth-order) constant term in the model. Most of the complexity of R2R control science lies and will continue to lie in extensions to support practical application of R2R control in semiconductor manufacturing facilities of the future; these extensions include support for weighting and bounding of parameters, run-time modeling of a large number of disturbance types, and incorporating prediction information such as virtual metrology and yield prediction into the control solution. As we move forward in the era of smart manufacturing and Industrie 4.0, R2R control will play a key role in the microelectronics manufacturing ecosystem as a process digital twin.

► [Real-Time Optimization of Industrial Processes](#)

Introduction

The semiconductor manufacturing industry involves the processing of semiconductor “wafers” using a variety of physical and chemical processes to produce dies or “chips” that contain a number of nanometer size features organized in layers. As feature sizes shrink, the industry must innovate to maintain acceptable product yield and throughput. One effective dimension of innovation that has been utilized since the early 1990s is model-based process control. The use of this technology in semiconductor manufacturing has been largely industry specific due to unique industry requirements and been given the name “run-to-run (R2R) control.”

R2R control is defined as “...a form of discrete process and machine control in which the product recipe with respect to a particular machine process is modified *ex situ*, i.e., between machine ‘runs,’ so as to minimize process drift, shift, and variability” (Moyné et al. 2000). (The “recipe” is the group of process settings for a process or process step, e.g., temperature, flow, and pressure.) The term “R2R control” was coined in the early 1990s in the semiconductor industry as the industry struggled to come up with mechanisms to keep critical semiconductor manufacturing processes such as chemical vapor deposition (CVD), chemical mechanical polishing (CMP), and reactive ion etching (RIE) under control. The processes are highly unobservable and are subjected to a number of disturbances. However, many of these disturbances can be modeled or tracked as they create measurable shifts in the process (e.g., after a maintenance operation) or gradual drifts in the process (e.g., chamber wall “seasoning” of an etch process over time, resulting in polymer buildup on chamber walls, causes changes to the operational effectiveness of the tool). Process and product quality is generally assessed through metrology measurements made *ex situ*, i.e., after the process is complete; examples of post-process metrology parameters are wafer average deposited or removed film thickness and film uniformity. R2R control generally uses statistically developed models of tool process

operation updated or “tuned” with process metrology feedback information on a “run-to-run” basis to keep the process under control and process quality high, in the face of these process drifts and shifts, as shown in Fig. 1. Note that the granularity of control could be wafer-to-wafer, batch-to-batch (“lot-to-lot”), etc.

Run-to-Run Control Approach

Because the processes are highly unobservable and dynamic, rather simple model forms are usually employed with filtering techniques used to track process shift and drift. The most commonly utilized R2R controller in the industry is the exponentially weighted moving average (EWMA) controller. The algorithm uses a linear model with an additional constant term. (Equations will use the following notation: arrays of vectors will be capitals, vectors will be lower case, and indexing within a vector or matrix will be lower case with subscripts. In addition, the special subscript “t” will be reserved for time or run number information.)

$$Y = Ax + c \quad (1)$$

where:

y = System output,

x = Input (Recipe),

A = Slope coefficients for equation,

c = Constant term for linear model.

Each output represents a target of control (usually measured by pre- and post-process metrology tools), and each input represents an adjustable parameter in the recipe.

$$\begin{aligned} y_1 &= a_{11}x_1 + a_{12}x_2 + \dots a_{1m}x_m + c_1 \\ &\dots \\ y_n &= a_{n1}x_1 + a_{n2}x_2 + \dots a_{nm}x_m + c_n \end{aligned} \quad (2)$$

The models are generally developed by executing a design of experiments (DOE), where the process area is explored with respect to the allowed variation of the process inputs by

Run-to-Run Control in Semiconductor Manufacturing, Fig. 1 Input/output structure of a typical R2R control solution

processing wafers with various input settings (see, e.g., Box and Draper 1987). Statistical packages are then used to determine the base model of the form described in (1) at the normal process operating point. As the processes are dynamic, the base model is updated on a “run-to-run” basis to compensate for model error. The algorithm operates under the assumption that the underlying process is locally approximated by a first-order linear polynomial model in the form of equation (1) and that this polynomial model can be maintained near a local optimal point solely by updating the constant term “c.”

The control process involves updating the model and then using that model to compute a recipe update. The model is updated by first comparing the actual process output, Y_t , to the model-predicted process output, AX_t . Using an EWMA filtering technique as an example, the constant term, c_t , can be updated as follows:

$$c_t = \alpha(y_t - Ax_t) + (I - \alpha)c_{t-1} \quad (3)$$

where α is a weighting factor between 0 and 1, often called a “forgetting factor.” Note that because of the additive nature of the EWMA series, the C_t calculation only requires knowledge (and storage) of the previous run measurements; this, combined with its relative simplicity, led to the widespread adoption of EWMA as the R2R controller filter of choice in this industry during the 1990s and early 2000s.

Once the model is updated, the process recipe is calculated. Since there are generally more inputs that can be tuned than outputs measured, the process is underdetermined, and there is an infinite solution space. Approaches such as Lagrange multipliers are used to determine the solution that is closest to the previous solution (Moyné et al. 2000).

Many extensions and alternatives to this basic approach have been developed and deployed over the past 10 years. These include (1) the replacement of EWMA filtering with other approaches such as the more general Kalman filtering, (2) explicitly modeling drift (termed “predictor corrector”), (3) modeling updates to first-order terms (in the “A” matrix), and (4) leveraging phenomenological models that capture process knowledge in equation forms, customized and tuned with statistical data. Perhaps the most important extensions to the basic approach involve addressing the practical issues associated with control systems application in this area. For example, providing capabilities for addressing bounding, weighting, and granularity (e.g., integer) of input and output settings often requires much more programming effort than supporting the core algorithm (Moyné et al. 2000).

Current Status and Future Extensions

Over the past 20 years, R2R control has evolved from a value-added capability applied to a few

processes to a required component to achieve cost and productivity competitiveness in most processes in the semiconductor manufacturing industries (IRDS 2018). As part of this evolution, a number of common trends in the R2R control space have emerged:

Support for fab-wide reusable and reconfigurable solutions for R2R control: As the benefits of R2R control were proven across multiple processes in semiconductor fabrication facilities, the focus turned to reusable and reconfigurable integrated “fab-wide” solutions for R2R control. The event-based capabilities described in Chapter 9 of Moyne et al. (2000) were leveraged to provide these solutions as they allow for integration and configuration of R2R control solutions to the particular application environment. This event-based approach has also been used to integrate R2R control with other capabilities such as fault detection and classification (FDC), work scheduling, and “virtual metrology” (see below), to provide another level of benefits toward improved product yield and throughput (Moyne 2004, 2009; Khan et al. 2007).

Movement to more granular control: The ever more stringent requirements on product quality are being addressed in large part by a movement from batch-level control (often called “lot-based control” in this domain), to wafer-level control (usually called “wafer-to-wafer” (W2W) control), to within-wafer (WIW) control. Although the granularity has changed, the basic approach to control has not. It is important to note that the improvement in quality associated with this trend results mostly from the use of pre-(process) metrology to reject incoming product disturbances, rather than post metrology to address the dynamics of the plant model (Moyne et al. 2000; IRDS 2018).

Support for control across multiple recipes using “single-threaded control”: Semiconductor manufacturing process control systems are characterized by a number of disturbance types that usually can be modeled as independent from the base process model and from each other. Perhaps the most common type of disturbance that is addressed is recipe or product change. When there is a change in product and related product

recipe, a single-process model must be adjusted to capture this disturbance while maintaining knowledge of process drift and/or shift. Oftentimes this process disturbance can be modeled as a shift to the overall process. Thus, the process model of Eq. (1) can be adjusted to the following:

$$Y = Ax + c_1 + c_2 + c_3 + \dots + c_n \quad (4)$$

where:

$c_1, c_2, \dots, c_{n-1}$ = constant terms associated with modeled disturbances such as product

c_n = constant term associated with process dynamics (drift and shift)

$c_1 + c_2 + \dots + c_n = c$ in Eq. (1)

Approaches have been devised for the assessment of c_i associated with a particular disturbance type (Edgar et al. 2004; Zou 2013); the result is that a single control model can be used across multiple product recipes and other disturbance types.

Enhancing R2R control with “virtual metrology”: Ex situ metrology plays a crucial role in semiconductor manufacturing as it is often the only source of product quality data before and after a process. However, given its high capital equipment cost and cycle time impact on critical processes, optimizing metrology by minimizing wasteful use and optimizing measurement value is important. Virtual metrology (VM) is a technology rapidly gaining acceptance in the marketplace as an efficient and cost-effective way to optimize and augment metrology value. VM is a modeling and metrology prediction solution, whereby process and product data, such as in situ fault detection (FD) information and upstream metrology information, is correlated to post-process metrology data. This same data can then be used to predict metrology information when conventional metrology data is not available (Khan et al. 2007; Cheng et al. 2011).

One of the uses of VM that is expected to become prominent over the next decade is in support of enhanced R2R control. As shown in Fig. 2, fault detection (FD) summary information is used along with adaptive VM modeling to

Run-to-Run Control in Semiconductor Manufacturing, Fig. 2 Virtual metrology enhanced R2R control

predict metrology information. The VM predictions are then used to fill in the measurement gaps in feed-forward and feedback control, thus enabling wafer-to-wafer or even within-wafer control. One of the research challenges is to optimally tune the control to best utilize both the real and predicted metrology information. This requires that VM data contain information on predicted measurement data quality (Khan et al. 2007).

$u(n)$ Tunable process inputs

$v(n)$ FD summary information

$y(k)$ Metrology measurement data for measured wafers

$\hat{y}(n)$ Predicted metrology measurements for all wafers

$\alpha_1(n)$ Feedback filter coefficient for feedback of measured data

$\alpha_2(n)$ Feedback filter coefficient for feedback of predicted data

Movement toward interprocess and eventually fab-wide control: The generally accepted vision of the future of advanced process control (APC) in general is a fabrication-wide fully integrated solution that incorporates all of the APC capabilities (R2R control, FDC, fault prediction, and statistical process control) as well as predictive capabilities such as predictive scheduling, predictive maintenance, virtual metrology, and predictive yield (IRDS 2018). Opportunities for research and development exist with the integration of these technologies, especially as the powers of the predictive domain are tapped. For

example, it is expected that R2R control will eventually incorporate predicted yield as a target with feedback to multiple coordinated process controllers (Moyné and Schulze 2010). Thus, the future of research in R2R control, while evolving, should remain strong in the coming years.

Summary and Future Directions

R2R control is a form of adaptive model-based process control that is tailored to environments where the process is discrete, dynamic, and highly unobservable; this is characteristic of processes in the semiconductor manufacturing industry. R2R control has evolved from a strictly research effort in the early 1990s to a required facility-wide capability in all of semiconductor manufacturing. It generally has, at its roots, a rather straightforward approach to adaptive model-based control. Most of the complexity of R2R control science lies and will continue to lie in extensions to support practical application of R2R control in semiconductor manufacturing facilities of the future.

The science of R2R control will continue to expand as the academic and industry communities look to incorporating capabilities that will allow R2R control to continue to be an integral part of the fabrication facility of the future. One key research direction over the next decade is the development of approaches for incorporating virtual metrology and yield prediction into control solutions. Other focus areas will likely include

hybrids of R2R control and continuous process control, learning mechanisms for single-threaded control in “high-mix” environments where there are a large number of disturbances that should be modeled, phenomenological R2R control models, and model libraries that combine stochastic information with process physics and chemistry knowledge, control solutions that are more directly optimized to financial parameters such as yield and throughput, and R2R control solutions that incorporate other analysis capabilities, such as FDC, either algorithmically or via event-based control rule approaches.

R2R control technology will also play an important role in the efforts associated with the move to smart manufacturing and Industrie 4.0 (Thoben et al. 2017; Moyne and Iskandar 2017). Specifically, R2R control is considered a process digital twin (DT), with R2R controllers becoming an integral part of a Smart Manufacturing DT framework (Qamsane et al. 2019). This integration will help facilitate the exploration of R2R control opportunities in other domains such as process commissioning and maintenance recovery, supply chain control and optimization, and control to fabrication facility yield objectives, but also to end-user yield (often termed latent yield) objectives. Additionally, the DT framework will allow R2R controllers to be integrated with other DT types; for example, combining R2R control and scheduling/dispatch DTs can allow for the inclusion of process quality metrics in scheduling/dispatch optimization decisions (Lopez et al. 2017). Each of these topics provides significant opportunity for research as well as benefit in application to the semiconductor manufacturing ecosystem.

Safety Guarantees for Hybrid Systems

Raphael M. Jungers¹ and Nikolaos Athanasopoulos²

¹UCLouvain, ICTEAM Institute, Louvain-la-Neuve, Belgium

²School of Electronics, Electrical Engineering and Computer Science, Queen's University Belfast, Belfast, UK

Abstract

Hybrid systems describe processes that typically need to satisfy a set of strict physical, computation, and communication constraints. Mission-critical and time-critical cyber-physical systems are a prime example where these constraints play a key role in analysis, controller synthesis, and implementation. On top of classical notions such as stability, safety plays a major role in the control design of hybrid systems. There is a long history of methods related to the safety analysis and safety enforcement for dynamical systems, with the ones concerning linear systems being more mature than the others. Due to the importance and complexity of the underlying problem, several different techniques have

been developed for hybrid systems. This entry summarizes the most important approaches and tools, together with references for further reading.

Keywords

Hybrid systems · Safety · Verification · Reachability · Abstraction · Hybrid automata · Switching · Lyapunov methods · Formal methods

Introduction

More and more applications use advanced, data-driven, decentralized, nonlinear control solutions for uncertain or complex models. This complexification leads to unavailability of classical guarantees on the system's behavior. Safety-critical control is a leading challenge in hybrid and cyber-physical systems. Examples can be found in (air) traffic control, medicine, drug administration, logistics and supply chain networks, robotics, planning, the smart grid, autonomous vehicles and autonomous navigation, digital manufacturing and Industry 4.0, control over networks, and edge and cloud computing. Safety analysis of such systems is extremely difficult, with negative complexity results holding even for simple hybrid dynamics, for example, discrete-time switching systems (Jungers 2009) and rectangular hybrid automata (Doyen et al. 2018). Many different approaches have been established to address

R.J. and N.A. are supported by the CHIST-ERA 2018 project DRUID-NET "Edge Computing Resource Allocation for Dynamic Networks"

the problem of safety, often leading to semi-algorithms with asymptotic properties. In view of the hardness of the task, it is critical to identify particular features of the system, which could make safety problems easier than in the general case. Indeed, for several special cases of hybrid systems, decidability or semi-decidability results are available. Let us mention reachability for timed automata, or the stability problem for switching systems (see, respectively, (Alur and Dill 1994; Jungers 2009), and (Doyen et al. 2018, Section 30.3) for precise statements). However, as a rule of thumb, one can argue that even elementary safety problems on very simple hybrid systems are often extremely hard.

Models

A *hybrid system* is a dynamical system consisting of both discrete (discrete event) and continuous dynamics, along with the corresponding sets where these two different dynamics are defined, often called *flow* and *jump* sets. A formal definition together with conditions for the existence of solutions is in Goebel et al. (2012, Sec. 1.1), covering, among others, switching and impulsive systems, and hybrid automata. For equivalence results between classes of hybrid systems, see Heemels et al. (2001), and for a formal definition for hybrid automata, see Doyen et al. (2018, Sec. 30.2.2). In this entry we consider the simple, however not restrictive, mathematical model representation

$$\begin{cases} \dot{x} = f(x, u, w), & x \in C, \\ x^+ = g(x, u, w), & x \in D, \end{cases} \quad (1)$$

where $x \in \mathcal{X} \subseteq \mathbb{R}^n$ is the state vector, defined in a space that may consist of both discrete and continuous variables, $C \subset \mathbb{R}^n$, $D \subset \mathbb{R}^n$, $D \cap C = \emptyset$, are subsets of the state space and $u(t) \in \mathcal{U}$ and $w(t) \in \mathcal{W}$ are the control and exogenous inputs, respectively. We denote the solution of the system at time t^* for an initial condition $x_0 \in \mathcal{X}$ with $x(t^*; x_0)$. Further details on the model, as well as conditions and subtleties on the existence of solutions of (1), can be found in Goebel et al. (2012).

Safety

Safety is at the heart of many verification problems of hybrid systems. To introduce the concept, we first define the notion of *reachability*; a set $\mathcal{X}_e$ is *reachable* from x_0 if the state can reach $\mathcal{X}_e$ from x_0 after some finite time t , i.e., if $x(t; x_0) \in \mathcal{X}_e$. The notion of safety is related to *avoiding* regions of the state space; given a set of *unsafe states* $\mathcal{X}_f$ and a set of initial states $\mathcal{X}_0$, a system is *safe* if for any initial state x_0 in the set $\mathcal{X}_0$, there exists a sequence of actions such that it never reaches $\mathcal{X}_f$, i.e., $x(t; x_0) \notin \mathcal{X}_f$, for all $t > 0$ and all $x_0 \in \mathcal{X}_0$. We note that safety is meaningful also in the absence of control inputs, in the context of system analysis.

Safety Verification and Safety-Critical Control

As already mentioned, the literature on safety analysis for hybrid systems is huge, with ramifications in Mathematics, Computer Science, Robotics, etc. In the rest of the note, an attempt is made to address the challenge of classifying and briefly surveying the existing approaches. The following subsection presents perhaps the major and more natural technique, namely, set propagation. Next, optimization-based methods are presented, followed by an exposition of formal methods, which have received a strong influence from the Computer Science literature. The last subsection discusses probabilistic methods that seem particularly promising at the era of data-driven systems and massive computations.

Set Propagation Methods

Safety is connected to non-violation of constraints in the state space. Thus, a natural way of verifying it is to propagate relevant sets, e.g., constraint/initial/target sets, across time. This is called *reachability analysis* or *set propagation*.

Reachability analysis, e.g., Aubin et al. (2011), is strongly related to dynamic programming. In control, the connection has been made obvious and exploited with the model predictive control (MPC) paradigm and the utilization of

invariant sets for the enforcement of recursive feasibility, stability, and optimality for closed-loop control systems. Depending on whether one considers the propagation of dynamics of the system forward or backward in time, reachability may be utilized for different objectives, such as computing invariant sets and designing controllers (Blanchini and Miani 2008, Sections 5, 6), reaching a target set, verifying safety from an initial set, or satisfying more complex temporal specifications and objectives (Belta et al. 2017). We present below two popular instances of forward and backward reachability maps, noting however that several variants exist, which serve slightly different objectives and purposes.

Forward Reachability

Forward reachability can be utilized to study where the trajectories of the system will lie in the future when starting from some set of initial conditions of interest. Here, we restrict to systems with only exogenous inputs $w(\cdot)$, as it is the most common case where these mappings are utilized in the literature. Given an initial set $\mathcal{X}_0$, the approach consists in generating the sequence $\{\mathcal{R}_i\}$ (adapted from Doyen et al. 2018, Sec. 30.4.1) with

$$\mathcal{R}_{i+1} = \mathcal{R}_i \cup \mathcal{F}_C(\mathcal{R}_i) \cup \mathcal{F}_D(\mathcal{R}_i), \quad (2)$$

$\mathcal{R}_0 = \mathcal{X}_0$, and

$$\begin{aligned} \mathcal{F}_C(\mathcal{R}_i) &= \{x(t^*; x_0) : (\exists x_0 \in \mathcal{R}_i \cap C, \exists w(t) \in \mathcal{W} : x(t; x_0) \in C, t \in [0, t^*])\}, \\ \mathcal{F}_D(\mathcal{R}_i) &= \{g(x_0, w) : x_0 \in \mathcal{R}_i \cap D, w \in \mathcal{W}\}. \end{aligned}$$

If all elements $\mathcal{R}_i$ of the generated sequence do not intersect with the set of unsafe states, i.e., $\mathcal{R}_i \cap \mathcal{X}_f = \emptyset$, then the system is safe.

Backward Reachability

Going backwards in time, we can define the sequence (adapted from Aubin et al. 2011, Sec

1.2.1.1, Viability Kernel) $\{\mathcal{C}_i\}$ generated by

$$\mathcal{C}_{i+1} = \mathcal{C}_i \cap (\mathcal{B}_C(\mathcal{C}_i) \cup \mathcal{B}_D(\mathcal{C}_i)), \quad (3)$$

with $\mathcal{C}_0 = \mathcal{X} \setminus \mathcal{X}_f$, and

$$\begin{aligned} \mathcal{B}_C(\mathcal{C}_i) &= \{x_0 \in C : (\exists t^* \geq \kappa, \exists u(t) \in \mathcal{U}, \forall t \in [0, t^*] : x(t; x_0) \in C \setminus \mathcal{X}_f, x(t^*; x_0) \in \mathcal{C}_i)\}, \\ \mathcal{B}_D(\mathcal{C}_i) &= \{x_0 \in D : (\exists u \in \mathcal{U} : g(x_0, u, w) \in \mathcal{C}_i)\}. \end{aligned}$$

In the formula above, κ is an arbitrary positive constant, essentially limiting the dwell time for the continuous-time dynamics. Let us add that it is assumed in the formula above that the value u of the controller is valid for any possible value of w ; however one can model different situations, where, e.g., the controller knows the input noise. If the limit of the generated sequence exists and is not empty, then the system is safe within this limit set, in the sense that all trajectories starting from it can be controlled such that they do not enter the unsafe region. Together with answering the safety problem, a by-product of the sequence is the establishment of safe, set-valued controllers, see, e.g., (Tomlin et al. 2003; De Santis et al.

2004). Moreover, many connections to Lyapunov theory through the notions of invariance and set contractivity have been identified (Blanchini and Miani 2008; Belta et al. 2017). We also remark that in the literature, different notions of safety/invariance have been developed, depending on the knowledge of the controller of the states, outputs, and exogenous inputs. Moreover, problems closely related to safety, such as the reach-avoid problem, can be addressed by changing the set $\mathcal{C}_0$.

Computations

Reachability analysis produces sequences of sets generated by recursive updates. Thus, it

is crucial to work with set parameterizations that can be described in a computer program with finite memory, and such that all operations described above are practically implementable. Polyhedral sets, especially in cases where linear dynamics and convex constraints are involved, are particularly appealing, since they are closed under Minkowski addition, intersection, convex union, and affine transformation. There is extensive literature tackling a great deal of settings involving linear dynamics and polyhedral sets, including linear parameter varying systems and switching systems. Nevertheless, even for the linear-convex case, computational complexity of the resulting sets can explode, especially for Minkowski sums, projections, minimal representations, and conversions between half-space and vertex representations, see, e.g., Fukuda (2004). A number of works deal with this issue by providing efficient alternatives using, e.g., zonotopes (Girard 2005), support function representations, and other classes of parameterized polytopes/template polyhedra. On the other hand, semialgebraic sets can also be employed for reachability analysis, such as ellipsoids, sublevel sets of SOS polynomials, or polynomials in the Bernstein representation. Moreover, one can leverage combinatorial techniques to reduce computational complexity in reachability analysis (Athanasopoulos and Jungers 2018).

Software

A number of fairly robust software solutions are available, often accompanied by modeling interfaces that allow easy formulation analysis and synthesis problems for hybrid systems and complex specifications. For toolboxes related to reachability analysis, we mention *SpaceEx*, *HyPro*, *CORA*, *d/dT*, and *JuliaReach* and note that the *MPT3* and *PPL* toolboxes are suitable for polyhedral computations.

Lyapunov-Based Optimization Techniques

The development of interior point optimization methods, enabling the efficient resolution of *linear matrix inequalities* (LMIs), has unlocked a huge literature in control. Linear matrix

inequalities are particular algebraic optimization problems involving linear functions of the variables, and these variables can be nonnegative real numbers or positive definite matrices. In the 2000s, it was realized that the ability to efficiently solve such optimization problems actually allows to solve much more general ones, where the unknown variables are multivariate polynomials (of a fixed bounded degree), involving linear functions of these polynomials together with constraints requiring nonnegativity of these polynomials. This is the so-called sum-of-squares (SOS) programming (Parrilo 2000).

This new optimization technique had a great impact on *state-space methods* in control: State-space methods encode the objective function and the constraints directly in terms of the time, and of variables in the state space, by opposition to frequency domain techniques. In view of the intrinsic nonlinear and nonstandard behavior of hybrid systems, it is not surprising that such methods are well-adapted to solve control problems for hybrid systems (Parrilo 2000; Coogan and Arcak 2012). Even more, polynomials turn out to be efficient tools for representing *sets of points* in the state space. As a simple example, if, for some given multivariate polynomial $p(x)$, one defines the set

$$\mathcal{X}_p := \{x \in \mathbb{R}^n : p(x) \geq 0\},$$

then one can encode a sufficient condition for a safety constraint of the type $\forall x \in \mathcal{X}_p, Ax \in \mathcal{X}_q = \{x \in \mathbb{R}^n : q(x) \geq 0\}$ in the following formula:

$$\forall x \in \mathbb{R}^n, q(Ax) \geq p(x).$$

The above formula is *LMI-representable*, being composed of linear functions of the polynomials p, q . By combining such constraints, one can encode complicated control objectives in large SOS programs, which are then solved by standard LMI solvers (e.g., MOSEK, SeDuMi, or SDPT3). Last, we should mention the closely related class of barrier methods; see, e.g., Prajna and Jadabaie (2004), Sloth et al. (2012) and Maghenem and Sanfelice (2019).

Technicalities

Classical results from algebraic geometry imply that polynomials are universal, in the sense that they can approximate arbitrarily well any set, at the price of increasing the degree of the polynomial; see Henrion and Korda (2014) and references therein. This directly translates to universality of the SOS approach for representing sets in the state space.

It is important to mention that inequalities of the type $\forall x, p(x) \geq 0$ are in fact *not* efficiently solvable by LMI solvers. Instead, one classically proceeds to a *SOS relaxation*, requiring the weaker condition that the polynomial can be expressed as the sum of squares of other polynomials. This latter condition can be solved efficiently. Even though this relaxation induces conservativeness, one can show that by increasing the degree of the polynomial, the SOS relaxation is asymptotically non-conservative (Fig. 1).

Interior point methods are relatively efficient at solving sum-of-squares programs, as they essentially rely on the Newton method for convex functions optimization and hence have a cubic complexity at every step; see Boyd and Vandenberghe (2004, Section 11.5) for a detailed analysis. However, one should note that in practice, they suffer scalability issues for problems of moderate to large size. Even more, the size of the SOS program depends on the number of monomials of the maximal degree chosen for the unknown polynomials. Since this number of monomials grows exponentially with the degree, in practice, one is bound to limit the degree to a reasonable value (say, from 8 to 14, depending on the problems considered).

Scalability Improvements

Recent work has focused on addressing the scalability issues. Of particular relevance for hybrid systems is the *path-complete approach* which, rather than increasing the degree of the polynomial, makes use of a combinatorial tool in order to enhance the representing power of polynomials by limiting their degree to a small number (Philippe et al. 2019). See Legat et al. (2018) for an application to safety-critical control of hybrid systems. Let us also mention the DSOS

approach (Ahmadi and Majumdar 2014) which restricts SOS problems to particular subfamilies of polynomials, on which solvers perform better.

Software

The past decade has seen the creation of efficient and easy-to-use software for encoding polynomial constraints in a high-level language that are then automatically transformed in LMI programs and solved. See Gloptipoly3, Jump, cvx, SOS-TOOLS, MOSEK, SeDuMi, and SDPT3, along with the parsers *Jump* and *YALMIP*.

Formal Methods and Abstraction

In view of the difficulty and criticality of safety problems, formal approaches have been proposed, influenced by the Computer Science and Model Checking communities. In these approaches, one formulates the safety problem in terms of rigorous predicates in a well-defined syntax corresponding to a particular logic. Typically, *first-order temporal logic* (Pnueli 1977) is well suited to formulate safety problems for dynamical systems, in particular hybrid systems. Then one needs to solve the logical equations formulated to verify safety of a given system or to construct an appropriate controller. To solve such complicated equations, one typically proceeds by *abstraction*, that is, by partitioning the state space into cells and the set of admissible inputs into small intervals, ending up with a finite-state automaton representing the dynamical system. Relying on standard continuity assumptions, many classical control problems (reachability, safety, reference tracking) can then be solved in a finite time, provided that the discrete abstraction satisfies *simulation* properties with respect to the actual system. The simulation property ensures that the behavior of the discrete, abstract system is a truthful representation of the original system. See Alur et al. (2000) for precise definitions. Thanks to the finiteness of the obtained abstraction, the above problems reduce to a simple graph-theoretic one. For example, one can just find (or optimize) a path in the obtained automaton in order to solve the control problem. This confers

Safety Guarantees for Hybrid Systems, Fig. 1

Example of the increasing performance of the SOS technique for a safe set computation problem, when one increases the degree of the unknown polynomial (in yellow for quadratic, orange for quartic, red for sextic,

and blue for octic) (Legat et al. 2018). The problem is concerned with finding the range of safe speeds for a truck with trailers. The pictures are projections of the safe set in the four-dimensional state space, onto coordinate planes

a great advantage to the method in theory. See Haghverdi et al. (2005) and Alur (2011) for good introductions to formal methods.

The formal approach as applied until now suffers from important scalability problems. Indeed, a straightforward discretization of the state space in small cells inevitably leads to a huge set of nodes/edges in the automaton. More precisely, the size of the discretization step must be small, because the method relies on a local property,

namely, continuity; and for a fixed discretization step, the number of cells grows exponentially with the dimension of the state space. For this reason, except for systems of very low dimension (3 or 4), the approach does not work in practice. Nevertheless, these techniques are considered as among the most promising opportunities for complex problems on hybrid systems and are at the center of an intense research effort for the moment.

Software

Several software solutions are being developed and constantly improved, as, for instance, *Pes-soa*, *CoSyMa*, *Tulip*, *SCOTS*, *Hytech*, *HSolver*, *Flow**, *PHAVer*, and *PHAVerLite* for general systems, *Uppaal*, *Kronos* for timed-automata oriented tools, and *Stochy* or *Prism* for probabilistic hybrid systems.

Probabilistic Techniques

Many models of hybrid systems are probabilistic. The techniques above can be adapted to such models, while specialized techniques have also been developed for the analysis of probabilistic hybrid systems; see Katoen (2016).

This subsection is not about such systems. Here we refer to probabilistic *techniques* that provide safety guarantees on either deterministic or probabilistic hybrid systems. Such techniques have recently received increasing attention as alternatives to the aforementioned methods, and the reason is obvious; due to the extreme computational cost, one may want to resort to probabilistic, Monte Carlo-like approaches to tackle the safety analysis problem while controlling at the same time the computational cost. In the community of systems and control, probabilistic techniques like the *scenario approach* (Calafiore and Campi 2006) are taking increasing importance. To our knowledge, the application of such approaches to hybrid systems has remained embryonic until now, but we expect a fast-growing body of work along these lines in the hybrid systems literature in the forthcoming years. Among such attempts, let us mention (Kenanian et al. 2019), which provides theoretical guarantees on probabilistic stability analysis for the particular case of switching systems, and (Julius and Pappas 2008) which makes use of stochastic bisimulation functions to provide a partial verification for more general hybrid systems.

In view of the intrinsic difficulty of coming with firm safety guarantees with probabilistic techniques, the state of the art of software implementation is less mature too. Let us mention S-Taliro which uses several randomized techniques for critical trajectory generation.

Summary and Future Directions

The problem of providing safety guarantees on a control system, called verification or model-checking in the Computer Science literature, is a paradigmatic problem that has been of paramount importance in applications for a long time. Today, the complexification of (data-driven, embedded, networked, etc.) control systems to hybrid systems makes it a challenge more than ever. It also makes it more important than ever, in view of the many emerging control systems interacting with our daily lives. In view of the theoretical computational barriers (undecidability, NP hardness, and others), one cannot hope that a single off-the-shelf technique could solve the problem, and as of today, ad hoc techniques have to be developed in order to cope with, and leverage, the specificities of the particular control problem at stake. Nevertheless, engineers have at their disposal several sound theoretical approaches, with solid software toolboxes, which can provide easily implementable solutions on simple models. We believe that in the future, these solutions will keep improving in performance and generality, as testified by the constant improvement on the state of the art over the past decades.

Sampled-Data H-Infinity Optimization

Tongwen Chen

Department of Electrical and Computer Engineering, University of Alberta, Edmonton, AB, Canada

Abstract

$\mathcal{H}_\infty$ optimization is central in robust control. When controllers are implemented by computers, sampled-data control systems arise. Designing $\mathcal{H}_\infty$ -optimal controllers in purely continuous time or in purely discrete time is standard in robust control; in this entry, we discuss the process of sampled-

data optimization, namely, designing digital controllers based on a continuous-time $\mathcal{H}_\infty$ performance measure.

Keywords

Computer control · $\mathcal{H}_\infty$ discretization · Robust control · Sampled-data systems

Introduction

Robust control deals mainly with controller design against uncertainties in system modeling and disturbances. The central tool used is $\mathcal{H}_\infty$ optimization.

In continuous time, consider the standard setup in Fig. 1, where G is the generalized plant and K is the controller; G has two inputs (w , the exogenous input, and u , the control input) and two outputs (z , the output to be controlled, and y , the measured output); K processes y to generate u . The $\mathcal{H}_\infty$ -optimal control problem is to design K to stabilize G and minimize the $\mathcal{H}_\infty$ norm of the closed-loop system in Fig. 1 from w to z , denoted T_{zw} . When both G and K are continuous-time, linear time-invariant (LTI), the $\mathcal{H}_\infty$ norm, $\|T_{zw}\|$, relates to the frequency response matrix $\hat{T}_{zw}(j\omega)$ as follows:

$$\|T_{zw}\| = \sup_{\omega} \bar{\sigma} [\hat{T}_{zw}(j\omega)],$$

where $\bar{\sigma}$ indicates the maximum singular value. This $\mathcal{H}_\infty$ -optimal control problem in the LTI case is solvable by many techniques, e.g., Riccati equations and linear matrix inequalities – see robust control textbooks by Zhou et al. (1996) and Dullerud and Paganini (2000).

Sampled-Data Control

When controllers are implemented by digital computers, periodic samplers and zero-order holds are used to model analog-to-digital and digital-to-analog conversion. Replacing K in Fig. 1 by sampler S (with period h), discrete-time controller K_d , and zero-order hold H

Sampled-Data H-Infinity Optimization, Fig. 1
Standard control setup in continuous time

Sampled-Data H-Infinity Optimization, Fig. 2
Sampled-data control setup

(synchronized with S), we obtain a sampled-data control system shown in Fig. 2; here, S converts y into a discrete-time sequence ψ ; K_d , a real-time algorithm in the computer, inputs ψ and computes another sequence v , which is converted by H into u .

There are in general three approaches to design a digital controller K_d : design a continuous-time controller K and then implement digitally via approximation, discretize the plant and then design K_d in discrete time, and finally, design K_d directly based on continuous-time performance specifications (Chen and Francis 1995). The last approach is followed in the $\mathcal{H}_\infty$ optimization framework.

Sampled-Data $\mathcal{H}_\infty$ Discretization

The sampled-data $\mathcal{H}_\infty$ control problem is to design K_d directly to stabilize G in Fig. 2 and minimize $\|T_{zw}\|$. Notice that even if G is LTI in

continuous time and K_d is LTI in discrete time, the closed-loop system T_{zw} is no longer LTI, due to the presence of S and H in the control loop; in this case, the $\mathcal{H}_\infty$ norm is interpreted as the $\mathcal{L}_2$ -induced norm:

$$\|T_{zw}\| = \sup\{\|z\|_2 : \|w\|_2 = 1\};$$

here, $\|\cdot\|_2$ represents the $\mathcal{L}_2$ norm on signals.

The sampled-data $\mathcal{H}_\infty$ control problem has been shown to be equivalent to a purely discrete-time $\mathcal{H}_\infty$ control problem (Kabamba and Hara 1993; Bamieh and Pearson 1992; Toivonen 1992); the process is known as sampled-data $\mathcal{H}_\infty$ discretization: for $\gamma > 0$, construct an LTI discrete-time system $G_{eq,d}$ connected to K_d as in Fig. 3; the two systems, T_{zw} in Fig. 2 and $T_{\zeta\omega} : \omega \mapsto \zeta$ in Fig. 3, are *equivalent* in that $\|T_{zw}\| < \gamma$ if $\|T_{\zeta\omega}\| < \gamma$, where the latter norm is ℓ_2 -induced, and since $T_{\zeta\omega}$ is LTI in discrete time, it equals the $\mathcal{H}_\infty$ norm of the corresponding transfer function $\hat{T}_{\zeta\omega}(z)$. Thus, pure discrete-time techniques are immediately applicable.

There are several ways to present this discretization. However, the computation is quite involved and hence is not given here; interested readers can find details in the papers by Kabamba and Hara (1993), Bamieh and Pearson (1992), and Toivonen (1992), or the book by Chen and Francis (1995). Note that the $\mathcal{H}_\infty$ discretization process is not quite *exact* in the sense that $G_{eq,d}$ depends on γ (Chen and Francis 1995).

Sampled-Data H-Infinity Optimization, Fig. 3 The equivalent discrete-time system

Summary and Future Directions

In sampled-data $\mathcal{H}_\infty$ optimization, the key idea is to address the hybrid nature of the problem, considering intersample behavior in formulation; the main tool is the so-called continuous lifting (Yamamoto 1994; Bamieh and Pearson 1992), making use of periodicity of sampled-data systems.

The ideas and tools developed in sampled-data control theory are still being used in emerging areas such as hybrid systems and networked control systems. For example, in event-triggered control systems, information exchange and control updating are not time driven but are done by certain event-triggering schemes, resulting in necessarily nonlinear and time-varying closed-loop dynamics; the analysis and synthesis issues in such systems are still challenging.

Recommended Reading

The continuous-time $\mathcal{H}_\infty$ control problem and its solutions are discussed extensively in several textbooks, e.g., Zhou et al. (1996) and Dullerud and Paganini (2000). The discrete-time $\mathcal{H}_\infty$ control problem was solved via the approach of Riccati equations in Iglesias and Glover (1991). The sampled-data $\mathcal{H}_\infty$ control problem was solved simultaneously with different methods in Kabamba and Hara (1993), Bamieh and Pearson (1992), and Toivonen (1992); details of the solution discussed here can be found in the book by Chen and Francis (1995).

Abstract

For digital devices to interact with the physical world, an interface is needed that transforms the signals from analog to digital and vice versa. Ideal samplers and zero-order hold devices are incorporated to derive discrete-time models of continuous-time systems. State variable descriptions and transfer functions are used.

Keywords

Continuous-time approximations · Digital control · Discrete-time approximations · Quantization · Reconstruction · Sampled-data systems · Sampling

Introduction

Sampled-data systems are discrete-time models of continuous-time processes useful in the digital

control of continuous-time systems. A digital controller cannot communicate directly with a continuous system and an interface is needed.

Consider a continuous-time system having $u(t)$ as its input and $y(t)$ as its output.

A/D Converter: The continuous-time signal $y(t)$ is converted into a discrete-time signal $\{\bar{y}(k)\}$, $k \geq 0$, $k \in \mathbb{Z}$, which is a sequence of values $\{\bar{y}(0), \bar{y}(1), \dots\}$ determined by the relation

$$\bar{y}(k) = y(t_k). \quad (1)$$

This is the ideal A/D (analog to digital) converter that samples $y(t)$ at times $t_0, t_1, t_2 \dots$ producing the sequence $\{y(t_0), y(t_1), \dots\}$ also denoted as $\{y(t_k)\}$.

D/A Converter: The D/A (digital to analog) converter receives as its input a sequence $\{\bar{u}(k)\}$, $k = 0, 1, 2, \dots$ and outputs a (piecewise) continuous-time signal $u(t)$ determined by

$$u(t) = \bar{u}(k), \quad t_k \leq t < t_{k+1}, \quad k = 0, 1, 2, \dots \quad (2)$$

That is, this D/A converter keeps the value of $u(t)$ constant at the last value of the sequence entered, until a new value comes in. Such a device is called a zero-order hold (ZOH) device.

Higher-Order Hold

The ZOH device described above implements a particular procedure of *data reconstruction or extrapolation*. The general problem is as follows:

Given a sequence of real numbers $\{\bar{f}(k)\}$, $k = k_0, k_0 + 1, \dots$ derive $f(t)$, $t \geq t_0$ so that

$$f(t_k) = \bar{f}(k), \quad k = k_0, k_0 + 1, \dots$$

Clearly, there is a lot of flexibility in assigning values to $f(t)$ in between the samples $\bar{f}(k)$; in other words there is a lot of flexibility in assigning the *intersample behavior* in $f(t)$.

A way to approach the problem is to start by writing a power series expansion of $f(t)$ for t , $t_k \leq t < t_{k+1}$, namely,

$$f(t) = f(t_k) + f^{(1)}(t_k)(t - t_k) + \frac{f^{(2)}(t_k)}{2!}(t - t_k)^2 + \dots$$

where $f^{(n)}(t_k) = \frac{d^n f(t)}{dt^n} \big|_{t=t_k}$, that is, the n th order derivative of $f(t)$ evaluated at $t = t_k$ (assuming that the derivatives exist).

Now if the function $f(t)$ is approximated in the interval $t_k \leq t < t_{k+1}$ by the constant value $f(t_k)$ taken to be equal to $\bar{f}(k)$, then

$$f(t) = f(t_k) \quad (= \bar{f}(k)), \quad t_k \leq t < t_{k+1}$$

which is exactly the relation implemented by a ZOH. Note that here the zero-order derivative of the power series is used which leads to an approximation by a constant which is a zero-degree polynomial.

It is clear that more than the first term in the power series can be taken to approximate $f(t)$. If, for example, the first two terms are taken, then

$$\begin{aligned} f(t) &= f(t_k) + f^{(1)}(t_k)(t - t_k) \\ &= f(t_k) + \frac{f(t_k) - f(t_{k-1})}{t_k - t_{k-1}}(t - t_k) \\ &= \bar{f}(k) + \frac{\bar{f}(k) - \bar{f}(k-1)}{t_k - t_{k-1}}(t - t_k) \end{aligned}$$

for $t_k \leq t < t_{k+1}$, where an approximation for the derivative $f^{(1)}(t)$ has been used. The approximation between t_k and t_{k+1} is a ramp with slope determined by $f(t_k) = \bar{f}(k)$ and the previous value $f(t_{k-1}) = \bar{f}(k-1)$. Here the first-order derivative of the power series is used which leads to an approximation by a first-degree polynomial. A device that implements such approximation is called a *first-order hold (FOH)*. Similarly, we can define a *second-order hold*. Note that the formula of the above FOH is derived if we decide to use a first-degree polynomial to approximate $f(t)$ on $t_k \leq t < t_{k+1}$ and then enforce $f(t_k) = \bar{f}(k)$ and $f(t_{k-1}) = \bar{f}(k-1)$. This approach is known as *polynomial interpolation*.

Obtaining a continuous (or piecewise continuous) function from given discrete values may be seen as a *continualization procedure*. Contrast

this with the *discretization procedure* introduced by sampling earlier in this section.

The continuous-time system with input $u(t)$ and output $y(t)$ together with the interface A/D and D/A converters can be seen as a system that receives a sequence of values $\{\bar{u}(k)\}$ as its input and produces a sequence of output values $\{\bar{y}(k)\}$. A digital controller can receive the system output $\{\bar{y}(k)\}$ as input and produce a $\{\bar{u}(k)\}$.

Quantization: The sampled output $\bar{y}(k) \in \mathbb{R}$ and it can take on an infinite number of values. In a digital device, however, a variable can take on only a finite number of values – this is because of the finite wordlength that is of the finite number of bits in the registers. So for $\{\bar{y}(k)\}$ to be used by a digital controller, an additional step is needed, that is, $\bar{y}(k)$ needs to be quantized. Under quantization, for example, values 2.315, 2.308, 2.3 with a 0.1 quantization step are all represented as 2.3. Quantization is an approximation and for short wordlengths, fewer number of levels, may lead to significant errors. Here we do not consider quantization.

Discrete-Time Models

Let a linear, continuous-time, time-invariant system be described by

$$\begin{aligned} \dot{x}(t) &= Ax(t) + Bu(t), \\ y(t) &= Cx(t) + Du(t). \end{aligned} \quad (3)$$

If we consider some initial time t_k , its state response for $t \geq t_k$ is

$$x(t) = e^{A(t-t_k)}x(t_k) + \int_{t_k}^t e^{A(t-\tau)}Bu(\tau)d\tau. \quad (4)$$

In view of (2), in a ZOH the input $u(t)$ will remain constant and equal to $u(t_k) (= \bar{u}(k))$ for a time period $t_{k+1} - t_k$. So

$$x(t) = e^{A(t-t_k)}\bar{x}(k) + \left[\int_{t_k}^t e^{A(t-\tau)} B d\tau \right] \bar{u}(k), \quad (5)$$

where $\bar{x}(k) = x(t_k)$, $\bar{u}(k) = u(t_k)$. For $t = t_{k+1}$, (5) becomes

$$\bar{x}(k+1) = \bar{A}(k)\bar{x}(k) + \bar{B}(k)\bar{u}(k) \quad (6)$$

where $\bar{A}(k) \triangleq e^{A(t_{k+1}-t_k)}$ and $\bar{B}(k) \triangleq \int_{t_k}^{t_{k+1}} e^{A(t_{k+1}-\tau)} B d\tau$.

Consider now the output $y(t)$ and assume that it is sampled at times t'_k that do not necessarily coincide with the instants t_k at which the input is adjusted ($t_k \leq t'_k < t_{k+1}$). Then if $\bar{y}(k) \triangleq y(t'_k)$,

$$\bar{y}(k) = \bar{C}(k)\bar{x}(k) + \bar{D}(k)\bar{u}(k), \quad (7)$$

where

$$\begin{aligned} \bar{C}(k) &= C e^{A(t'_k - t_k)} \\ \bar{D}(k) &= C \left[\int_{t_k}^{t'_k} e^{A(t'_k - \tau)} d\tau \right] B + D. \end{aligned}$$

In the case when all $k = 0, 1, 2, \dots$, $t'_k = t_k$ and $t_{k+1} - t_k = T$ a constant period, called the *sampling period*. Then the sampled-data system is given by

$$\begin{aligned} \bar{x}(k+1) &= \bar{A}\bar{x}(k) + \bar{B}\bar{u}(k) \\ \bar{y}(k) &= \bar{C}\bar{x}(k) + \bar{D}\bar{u}(k) \end{aligned} \quad (8)$$

where

$$\begin{aligned} \bar{A} &= e^{AT}, \quad \bar{B} = \left[\int_0^T e^{A\tau} d\tau \right] B, \\ \bar{C} &= C, \quad \bar{D} = D. \end{aligned}$$

The intersample behavior of the continuous system can be determined using (5).

Example Let the continuous-time system be given by (3) where

$$A = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, B = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, C = [1 \quad 0], D = 0,$$

and let T denote the sampling period. The transfer function of the continuous-time system is $\hat{H}(s) = C(sI - A)^{-1}B = 1/s^2$, the double integrator. The discrete-time state-space representation of the system, which represents the continuous-time system preceded by a zero-order hold (D/A converter) and followed by a sampler [an (ideal) A/D converter], both sampling synchronously at a rate of $1/T$, is given by $\bar{x}(k+1) = \bar{A}\bar{x}(k) + \bar{B}\bar{u}(k)$, $\bar{y}(k) = \bar{C}\bar{x}(k)$, where

$$\begin{aligned} \bar{A} &= e^{AT} = \sum_{j=1}^{\infty} (T^j/j!) A^j = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \\ &+ \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} T = \begin{bmatrix} 1 & T \\ 0 & 1 \end{bmatrix}, \\ \bar{B} &= \left(\int_0^T e^{A\tau} d\tau \right) B \\ &= \left(\int_0^T \begin{bmatrix} 1 & \tau \\ 0 & 1 \end{bmatrix} d\tau \right) \begin{bmatrix} 0 \\ 1 \end{bmatrix} \\ &= \begin{bmatrix} T & T^2/2 \\ 0 & T \end{bmatrix} \begin{bmatrix} 0 \\ 1 \end{bmatrix} = \begin{bmatrix} T^2/2 \\ T \end{bmatrix}, \\ \bar{C} &= C = [1 \quad 0]. \end{aligned}$$

The transfer function (relating $\bar{y}$ to $\bar{u}$) is given by

$$\begin{aligned} \hat{H}(z) &= \bar{C}(zI - \bar{A})^{-1}\bar{B} \\ &= [1 \ 0] \begin{bmatrix} z-1 & -T \\ 0 & z-1 \end{bmatrix}^{-1} \begin{bmatrix} T^2/2 \\ T \end{bmatrix} \\ &= [1 \ 0] \begin{bmatrix} 1/(z-1) & T/(z-1)^2 \\ 0 & 1/(z-1) \end{bmatrix} \\ &\quad \begin{bmatrix} T^2/2 \\ T \end{bmatrix} \\ &= \frac{T^2}{2} \frac{(z+1)}{(z-1)^2}. \end{aligned}$$

If we focus on single-input, single-output systems and consider ideal sampler A/D and ZOH D/A, then given the transfer function $G(s)$ of the continuous system, there is a direct formula to determine the transfer function of its discrete approximation $H(z)$, namely,

$$H(z) = (1 - z^{-1})Z\{G(s)/s\}. \quad (9)$$

Here $Z\{G(s)/s\}$ means that first the inverse Laplace transform of $G(s)/s$ is taken to obtain $f(t) \triangleq [\mathcal{L}^{-1}(G(s)/s)]$. The function $f(t)$ is then sampled to obtain $f(kT)$, $k = 0, 1, 2, \dots$ and the z -transform of $f(kT)$ is evaluated. To illustrate, in the above example $G(s) = \frac{1}{s^2}$, $G(s)/s = \frac{1}{s^3}$, and $f(t) = \mathcal{L}^{-1}(\frac{1}{s^3}) = \frac{1}{2}t^2$, $t \geq 0$. Then

$$\begin{aligned} H(z) &= (1 - z^{-1})Z\{\frac{1}{2}(kT)^2\} \\ &= (1 - z^{-1})\frac{T^2}{2}Z\{k^2\} \\ &= \frac{T^2}{2} \frac{z+1}{(z-1)^3} \end{aligned}$$

as before.

Summary

Sampled-data systems arise in the digital control of systems and include both continuous and discrete-time dynamics. Discrete-time approximations of continuous-time systems using ideal samplers and ZOH devices were derived using state variable descriptions. Extensions include quantization and lead to hybrid dynamical systems which include both continuous and discrete variable dynamics.

A variation of the approach described in this entry of deriving sampled-data systems uses the discrete-time delta operator. This approach has the advantage that as the sampling period $T \rightarrow 0$, the discrete-time model reverts to the original continuous-time model, which is not the case with the more common approach described above.

Satellite Control

Finn Ankersen
European Space Agency, Noordwijk,
The Netherlands

Abstract

Spacecraft control systems are described for single and distributed space systems. The attitude dynamics is formulated including flexible and sloshing phenomena, followed by a description of attitude sensors and actuators. $\mathcal{H}_\infty$ and robust controls are formulated as

signal-based two degree-of-freedom control architectures. The equations are given for the relative motion dynamics between spacecraft on elliptical orbits with the generic Yamanaka-Ankersen state transition matrix. Formulations are provided for rendezvous and docking scenarios and formation flying control, maneuvers, avionics, and laser metrology systems together with the onboard autonomy needs.

Keywords

Flexible modes · Formation flying · Fractionated spacecraft · $\mathcal{H}_\infty$ control · Multivariable systems · Relative dynamics · Rendezvous and docking · Robust control · Sloshing · Spacecraft attitude control · Spacecraft position control

Introduction

This entry explains the control needs of spacecraft after they have been separated from the launch vehicle and injected onto their initial orbit.

Actuators and sensors are explained followed by the control objectives. The state-of-the-art control techniques and architectures are addressed.

Spacecraft are classically well-known physical systems that can be described by first principles. The advantage is fairly precise plant models and uncertainty characterization of physical parameters. This is well suited for a model-based control design approach.

Mission Types

From a control point of view, space missions can be split into two main categories according to which physical states need to be controlled:

Attitude Control: This is needed by any spacecraft irrespective of the mission objectives. Such missions are typically low earth orbit (LEO) missions for astronomy, observations, and, in higher orbits, constellations for navigation and communication. Further, there are

interplanetary and planetary exploration science missions. The pointing requirements vary from a few degrees to milli-arc seconds.

Relative Position Control: Within distributed space systems, this is relevant for rendezvous and docking (RVD) and formation flying (FF) missions. It leads to a 6 degree-of-freedom (DOF) control problem as the relative attitude is also needed. The former is mostly for missions to space station logistics infrastructures and the latter for scientific missions. Relative position can also be required during the final stages of controlled planetary landings. Another category is missions with ultrahigh control performance requirements, where the spacecraft platform and the science instrument need to be considered as one coupled system.

Attitude Control

Fundamentally the three attitude angles θ and angular rates ω need to be controlled to a certain reference. See Fig. 1 for definition.

The general rigid body dynamics expressed in a rotating frame(*), which is mostly the case when orbiting a central body, can be expressed as

$$\mathbf{N} = \frac{d^*(\mathbf{I}\omega^*)}{dt} + \omega \times \mathbf{I}\omega^* \quad (1)$$

where $\mathbf{I}$ is the constant inertia matrix, ω is the inertial angular velocity, and $\mathbf{N}$ is the torque acting on the spacecraft (Wie 1998).

The kinematics can be described by one of the 12 sets of Euler angles (can have singularities) or the hypercomplex quaternion vector (no singularities) (Hughes 1986).

The dynamics and kinematics equations need to be linearized and are in the general form of a coupled 12th order system. It is the fundamental model for the rigid body spacecraft control design.

Most modern spacecraft have large flexible appendices in the form of solar panels and large antennae reflectors. Fuel sloshing is a similar lightly damped oscillatory phenomena, which often needs to be taken into consideration.

Satellite Control, Fig. 1

Spacecraft body (*black*)
and reference (*red*) frames.
The frames coincide for
 $\theta = 0$

The incorporation of dynamic elements such as flexible panels, antennae, and sloshing fuel can be modeled by Eqs. (2) and (3) provided the overall rotation rate $\dot{\omega}$ and linear accelerations $\ddot{\mathbf{x}}$ are not too large.

$$\mathbf{M}_T \begin{bmatrix} \ddot{\mathbf{x}} \\ \dot{\omega} \end{bmatrix} = \begin{bmatrix} \mathbf{F} \\ \mathbf{N} \end{bmatrix} - \mathbf{L}\ddot{\eta} \quad (2)$$

$$\ddot{\eta}_k + 2\zeta_k \Omega_k \dot{\eta}_k + \Omega_k^2 \eta_k = -\frac{1}{m_k} \mathbf{L}^T \begin{bmatrix} \ddot{\mathbf{x}} \\ \dot{\omega} \end{bmatrix} \quad (3)$$

where

- $\mathbf{M}_T$: rigid body mass/inertia matrix
- $\ddot{\mathbf{x}}, \dot{\omega}$: linear and angular acceleration
- $\mathbf{F}, \mathbf{N}$: forces and torques on the spacecraft
- η_k : the k th flexible state
- ζ_k : the k th flexible damping factor
- Ω_k : the k th flexible eigen frequency
- m_k : the k th modal mass (normalized to 1)
- $\mathbf{L}$: participation matrix of the k th mode

For attitude only the second row of Eq. (2) is needed, but translation is included here for the sake of completeness and later use.

The sensors utilized are typically gyroscopes for measuring the inertial angular rate, sun sensors to measure orientation at low accuracy, and star trackers for high-precision angular attitude measurements. All of those sensors are linear in their normal operational range and it suffices to use bias noise models for synthesis. Gyros do need a drift estimation and compensation to

function properly over longer time. All sensors utilize redundancy for providing measurements around all three axes as well as providing fault tolerance. Some scientific observatory spacecraft use their telescopes for attitude measurements in order to obtain the required precision beyond the capability of star trackers.

The actuators producing pure torques are magnetic torquers, reaction wheels, and control momentum gyros. The last can produce large torques used for rapid slew maneuvers with little power. The last two types have nonlinear issues around low to zero speed due to friction issues. They accumulate angular momentum from asymmetric disturbances. This leads to a need for thrusters for angular momentum off-loading. Thrusters are also used to control the attitude directly on many spacecraft. They are mostly of on-off type, though continuous ones exist, and will need to be pulse width modulated (PWM) to obtain quasi-linear behavior. The nonlinear on-off nature needs to be taken into account for the control closed loop analysis. It is done by use of the negative inverse describing function (Ogata 1970) for stability analysis and nonlinear modeling for verification simulations in the time domain. For larger numbers of thrusters, an optimization-based selection algorithm is applied to the controller output.

Before using the plant model in Eq. (2) for a flexible spacecraft, a simpler multivariable model of a rigid spacecraft is used as in Eq. (4):

Satellite Control, Fig. 2 Robust control formulation, where Δ is the structured uncertainty, K is the controller, P the partitioned formulation of the plant with weights, and w and z are exogenous inputs and outputs, respectively

$$\dot{\mathbf{x}} = \begin{bmatrix} \mathbf{0} & \mathbf{B}_k \\ \mathbf{0} & \mathbf{A}_d \end{bmatrix} \mathbf{x} + \begin{bmatrix} \mathbf{0} \\ \mathbf{B}_d \end{bmatrix} \mathbf{N} \quad (4)$$

where $\mathbf{x} = [\theta_x, \theta_y, \theta_z, \omega_x, \omega_y, \omega_z]^T$, $\mathbf{B}_k$ is identity, $\mathbf{B}_d = \mathbf{I}^{-1}$, and $\mathbf{A}_d$ is the general Jacobian for the dynamics having a real right half-plane (RHP) pole. See Ankersen (2011). The model describes the angular deviation from some reference frame, whose orientation can be arbitrary. It uses the Euler (3, 2, 1) rotation in the kinematics.

The state of the art of attitude control is today mostly based on $\mathcal{H}_\infty$ type of robust controllers with synthesis performed in the frequency domain. Requirements are often specified in the time domain, but formal methods exist to transform them into frequency domain weighting functions (ESA Handbook 2011) enhancing both synthesis and analysis. System uncertainties can be formulated as structured linear fractional transformations (LFT) with a general control configuration as illustrated in Fig. 2.

Commonly the $\mathcal{H}_\infty$ controller K is designed, and the lower loop in Fig. 2 is closed via a lower LFT such that $\mathbf{N} = F_l(\mathbf{P}, \mathbf{K})$ and robust stability (RS) and robust performance (RP) analysis is performed on the $\mathbf{N}, \Delta$ system (Skogestad and Postlethwaite 1996).

On high performance pointing spacecraft, active vibration suppression of, e.g., cryocoolers is needed. The implementation of control design and recursive system identification can achieve

significantly better attenuation compared to classical passive isolation techniques.

Lately optimization-based codesign of structures and control has been performed successfully. A joint performance function is formulated (mass, stiffness, pointing, fuel, etc.) and an optimization is performed (differential evolution algorithm) iterating on control design and finite element models (FEM). A μ -synthesis controller is synthesized, the pointing performance is fulfilled, and 15–20 % mass saving is obtained on the flexible structures. The entire process is fully automated (Falcoz et al. 2013).

Relative Position Control

For all distributed space systems, relative dynamics is important. Rendezvous and formation flying missions need tracking or maintenance of the desired relative separation, orientation, and position between or among the spacecraft. This is common and independent of the mission type and will be described in general terms ahead of the specific RVD and FF missions.

The general relative position dynamics between centers of mass (COMs) is in Eq. (5), where it is observed that the in-plane motion (x, z) is decoupled from the out-of-plane motion (y).

$$\begin{aligned} \ddot{x} - \omega^2 x - 2\omega\dot{z} - \dot{\omega}z + k\omega^{\frac{3}{2}}x &= \frac{1}{m_c} F_x \\ \ddot{y} + k\omega^{\frac{3}{2}}y &= \frac{1}{m_c} F_y \\ \ddot{z} - \omega^2 z + 2\omega\dot{x} + \dot{\omega}x - 2k\omega^{\frac{3}{2}}z &= \frac{1}{m_c} F_z \end{aligned} \quad (5)$$

where $\omega = \omega(t)$ is the orbital angular rate, m_c is the chaser mass, F_{xyz} is the force on the chaser, and k is a constant determined by the orbit and is valid for any Keplerian orbit with eccentricity $\varepsilon < 1$.

The Yamanaka-Ankersen equations (Yamanaka and Ankersen 2002) provide the generalized homogeneous solution in the form of the transition matrix Φ , where the solution can be

Satellite Control,

Fig. 3 Definition of COM-to-COM and port-to-port positions, $\mathbf{s}$ and $\mathbf{s}_{pp}$, respectively, between two spacecraft

written as

$$\mathbf{x}(t) = \mathbf{\Lambda}^{-1}(\nu) \mathbf{\Phi}(\nu) \mathbf{\Phi}_0^{-1}(\nu_0) \mathbf{\Lambda}(\nu_0) \mathbf{x}(t_0) \quad (6)$$

where ν is the orbital true anomaly and $\mathbf{\Lambda}$ are transformation matrices to and from the time domain. The elements of $\mathbf{\Phi}$ in Eq. (6) are detailed in (Ankersen 2011), where relevant particular solutions are also to be found. Equation (6) reduces to the well-known Clohessy-Wiltshire equations for circular orbits ($\varepsilon = 0$) (Clohessy and Wiltshire 1960). Equation (6) is used for feedforward control and trajectory propagation in the guidance function. During the final approach (see Fig. 3), a model accounting for the docking port-to-port relative position and the couplings from the relative attitude to the position is utilized and formulated in Eqs. (7) and (8) (Ankersen 2011):

$$\mathbf{R} = \begin{bmatrix} \mathbf{A}_p & \mathbf{0} \\ \mathbf{0} & \mathbf{A}_c \end{bmatrix} \mathbf{x} + \begin{bmatrix} \mathbf{B}_p & \mathbf{0} \\ \mathbf{0} & \mathbf{B}_c \end{bmatrix} \mathbf{u} \quad (7)$$

$$\mathbf{y} = \begin{bmatrix} \mathbf{I} & \mathbf{0} & \mathbf{B}_{dc1} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} & \mathbf{0} & \mathbf{B}_{dc2} \\ \mathbf{0} & \mathbf{0} & \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{I} \end{bmatrix} \mathbf{x} \quad (8)$$

where $\mathbf{x} = [\mathbf{x}_p, \dot{\mathbf{x}}_p, \boldsymbol{\theta}_c, \boldsymbol{\omega}_c]^T$, $\mathbf{y} = [\mathbf{x}_{pp}, \dot{\mathbf{x}}_{pp}, \boldsymbol{\theta}_c, \boldsymbol{\omega}_c]^T$, index p refers to COM positions, index c to chaser attitude, index pp to port-to-port position, and $\mathbf{B}_{dc1}$, $\mathbf{B}_{dc2}$ are the coupling matrices of the docking port.

A relative motion scenario for a typical RVD mission looks like in Fig. 4. During the final approach ($<300\text{m}$ range), the chaser relative attitude and relative position are controlled. During the other phases, the chaser attitude is Earth pointing and the relative position is controlled at the station-keeping (SK) points, $s_0, \dots, s_4$ in Fig. 4. The trajectories are typically open loop feedforward controlled (often with midcourse corrections).

The avionics sensors for the attitude control part are generally similar to those described earlier under attitude control in connection with Fig. 1. Active laser CCD type of sensors is used to measure the relative position (range and line-of-sight (LOS) angles) and at short range ($<50\text{m}$) the relative attitude. They require a target pattern to provide precise measurements at short range. Accelerometers are used, particularly for pulsed maneuvers. The next generation of RVD GNC systems, test flown, will utilize Lidar, infrared cameras, and visual cameras in combination with advanced image processing providing RVD capabilities with both cooperative and passive target spacecraft.

The actuators are mostly thrusters arranged to achieve controllability for all the 6DOF maneuvers needed. Based upon the controller output, the active thrusters are selected by means of some type of fuel optimization algorithm. The selected thrusters are then pulse width modulated (PWM) within the sampling time.

The controllers are frequently of multivariable $\mathcal{H}_\infty$ type. They are similar to what is described

Satellite Control, Fig. 4 This figure shows the phases of typical relative motion approach. The shaded area is a keep-out zone (KOZ) defined for safety reasons. V-bar is the x-axis and R-bar is the z-axis

Satellite Control, Fig. 5 Principal structure of the 2 degree-of-freedom controller

in connection with Fig. 2. Flexible modes and in particular sloshing need to be taken into account using Eq. (2). Sloshing pendulum models are used during boost maneuvers and spring mass damper models during other modes. The couplings between relative attitude and relative position in Eq. (8) can be analytically decoupled setting the matrix $\mathbf{C}$ to identity and premultiplying with a decoupling matrix $\mathbf{V}_d$, such that

$$\mathbf{V}_d \mathbf{C} = \mathbf{I} \Leftrightarrow \mathbf{V}_d = \mathbf{C}^{-1} \quad (9)$$

and by the inversion theorem for partitioned matrices the upper right partition just changes sign. The designed controller then needs to be premultiplied by $\mathbf{V}_d^{-1}$, which facilitates a simpler control design maintaining the 6DOF performance after 2 times 3DOF synthesis.

A 2 degree-of-freedom control architecture as in Fig. 5 is beneficial since much of the performance is achieved by controller $\mathbf{K}_1$. The structure of the synthesis formulation is a signal-based model-reference configuration for the $\mathcal{H}_\infty$

control rather than the more classical mixed sensitivity type. It has proven to have higher robustness and performance for this type of applications. As an example, consider a controller that has to follow a sawtooth motion of the docking port of the International Space Station (ISS) with an amplitude of 0.4 m and reversal times of 8 s. The signal-based model-reference controller manages to track such a motion with errors less than 0.01 m compared to the best operational performance of 0.08 m.

Formation flying usually includes more than two spacecraft with the need to be controlled relative to each other. The objective of FF is to form an instrument in space, not possible with fixed structures, like a synthetic aperture or an interferometer of large size.

The performance needs are high and require innovative high-precision ($<1 \mu\text{m}$) metrology sensors. They are based on divergent laser beams for the coarse part to be able to transit from lower to higher accuracy. The fine metrology uses a laser beam and internal interferometers to reach the μm domain. Actuators are in the

range of μN thrust, which can be achieved with either cold gas or electrical propulsion thrusters.

The maneuvers realized by entire formations are rotation, resizing, and slew while maintaining the formation in most cases (Alfriend et al. 2010).

Formation flying missions with the highest performance requirements have optical payloads, which need to have internal control loops at component level. To reach the performance required for applications such as optical interferometry, the formation and payload must be considered as one system. The synthesis of a multivariable controller then handles all the cross couplings in the system needed to reach performance. Beyond flexible modes, such systems might also have a need for active vibration damping for systems using cryocoolers.

The GNC architecture is often centralized for nominal science operational modes. For the formation deployment and contingency situations, a decentralized control architecture is needed. This leads to a dual architecture GNC system in general for formation flying systems. The onboard autonomy needs to be fairly high in order to cope with the contingencies in the formation without ground intervention.

Finally there is an emerging concept of fractionated spacecraft. There, a formation consists of a large number of small simple vehicles maneuvering relative to each other fully autonomously based upon the nearest neighbor knowledge and not necessarily information about the entire formation (Cornford 2012).

Summary and Future Directions

The control of spacecraft has been described for pure attitude control needs and for spacecraft performing relative proximity maneuvers like rendezvous and formation flying. The focus has been on sensors, actuators, dynamics, and the robust control methods applied today.

The further development direction of the field is expected to be increased on board autonomy with replanning capabilities and fault-tolerant GNC designs. Model predictive control (MPC)

will enter in particular on the guidance functions. More integrated GNC system-level designs, of multidisciplinary nature, are expected.

Scale-Invariance in Biological Sensing

Eduardo D. Sontag

Departments of Bioengineering and Electrical and Computer Engineering, Northeastern University, Boston, MA, USA

Abstract

The phenomenon of fold-change detection, or scale invariance, is exhibited by a variety of sensory systems, in both bacterial and eukaryotic signaling pathways. This entry gives a short introduction to the subject.

Keywords

Perfect adaptation · Fold-change detection · Scale invariance

Introduction

It is often the case that a physiological signal returns to a pre-stimulus value after a transient input has been sensed. This input, for example, an impulse or pulse, could be physical or biochemical in nature. Examples are a ligand to an olfactory receptor or a light input to a photoreceptor. This is a stability property. A much more interesting phenomenon is that of *exact adaptation* to a persistent input, the subject of much investigation from both a modeling and experimental perspective (Alon 2007). This phenomenon occurs when the return to such a steady-state value of the output happens even in the face of a *sustained* step or periodic excitation. Physiological adaptation is a trait of many sensory systems. It allows them

to accurately detect changes in input signals and to distinguish meaningful information from background, by appropriately shifting their dynamic range. For example, the human eye distinguishes features across nine orders of magnitude, even though its sensors can only detect a three order of magnitude contrast; this is achieved through both the pupillary light reflex and the adjustment of sensitivity of rods and cones. Similarly, humans adapt to constant touches, smells, or background noises, detecting new information only when a substantial change occurs. At a cellular scale of behavior, a very well-studied example of physiological adaptation is that of the response of the *E. coli* chemotactic pathway response to stepwise addition and subsequent removal of attractant.

In terms of control theory, perfect adaptation can be thought of as a particular instance of *disturbance rejection*, which for linear systems is translated as zero gain at zero or other frequencies. Disturbance rejection implies, for linear as well as some classes of nonlinear systems, the existence of “internal models” of inputs (Huang et al. 2018). For simplicity, we restrict to step responses in this short discussion, but similar questions can be studied for persistent oscillatory inputs.

Scale Invariance

There is a finer property than mere adaptation, called scale invariance of responses or “fold-change detection”. To explain this property intuitively, consider two step inputs u_1 and u_2 which are scaled versions of each other: $u_2(t) = pu_1(t)$, for some positive number or “scale factor” p , see Fig. 1a. Adaptation means that, whether the input is u_1 or u_2 , the output will return to the same value (Fig. 1b). Scale invariance means that the entire actual transient response will be the same under either excitation (Fig. 1d). An intermediate property between mere adaptation and scale invariance is the “Weber-like” property in which temporal, transient responses may be different but peak intensities coincide (Fig. 1c). This intermediate property is one version of the Weber-Fechner law in psychophysics of human sensing, which relates physical magnitudes of

Scale-Invariance in Biological Sensing, Fig. 1 (a) Scaled step inputs and corresponding responses; (b) perfect adaptation; (c) Weber-like (same peak amplitude responses); (d) scale invariance (same transient responses)

stimuli to perceived intensities. Ernst Weber in the 1840s performed experiments in which subjects were asked to hold a weight, and the weight was gradually increased until a change was first noticed. He found that the smallest noticeable difference was proportional to the starting value, and not to the absolute weight: two scaled versions of the input result in the same reaction. A similar phenomenon has been observed in other sensory systems, including perception of pitch in sound, light intensity, smell, pain, and taste. Gustav Fechner went on to establish a logarithmic relation between physical and perceived quantities (Weber 1905).

A pair of papers published in late 2009 led to a focus on scale invariance in cell biology. These papers dealt with the Wnt and EGF signaling pathways, which are highly conserved eukaryotic signaling pathways that play roles in embryonic patterning, stem cell homeostasis, cell division, and other central processes, the misregulation of which results in diseases including several types of cancer. The paper Goentoro and Kirschner (2009) focused on the effect of binding of Wnt ligand on the levels of a key protein in the Wnt signal transduction pathway, β -catenin, which in turn activates transcription of specific target genes. It was observed that, in a given population, cells might differ substantially in the β -catenin level after stimulation by Wnt but that the effects downstream, measured either through gene expression or phenotype (in *Xenopus* embryos), appear to be a function only of the relative changes in Wnt, and not its absolute amount. Analogous results, for an EGFR pathway, were reported in the paper Cohen-Saidon et al. (2009). Scale invariance is also found in certain bacterial

signaling systems. A prediction, for the *E. coli* chemotaxis sensory circuit in response to the ligand α -methylaspartate, was made in Shoval et al. (2011), based on a model proposed by Tu, Shimizu, and Berg (2008). This prediction was later verified in a microfluidics population experiment carried out in Stocker's lab as well as an in FRET measurements on genetically altered bacteria in Shimizu's lab (Lazova et al. 2011).

Scale invariance means that the system cannot distinguish between an input $u(t)$ and a scaled version $v(t) = pu(t)$. For step inputs that jump at $t = 0$, we can reformulate this property by saying that the response can *only* depend on the “fold change” of the input at time 0: $v(t)/v(0) = pu(t)/pu(0) = u(t)/u(0)$, hence motivating the alternative terminology “fold change detection” (FCD). Another way to phrase this is that FCD systems only depend on $\log(u(t)) - \log(u(0))$, that is, on logarithmic changes in inputs (hence sometimes the use of the term “log sensing”).

Example: Feedforward Circuits

Let us focus on one rich source of practical examples of FCD systems, feedforward motifs. These circuits, popularized by the textbook Alon (2007), play a central role in metabolic pathways, signaling networks, and genetic circuits. Feedforward loops come in two flavors, coherent and incoherent. The *IFFL* (*incoherent feedforward loop*) motif, represented by the graphs in Fig. 2, is one of the two main biomolecular mechanisms (another is nonlinear integral feedback) that can lead to FCD (Goentoro et al. 2009; Shoval et al. 2010, 2011). In these circuits, the input u activates a regulatory variable (molecular species) x that in turn activates or represses a downstream

species y . Through a different path, the signal u represses or activates, respectively, the species y . This antagonistic (“incoherent”) effect endows the IFFL motif with powerful signal processing properties (Alon 2007). Similar circuits may play a role in how the immune system distinguishes between “self” and “nonself” antigens (Shoval et al. 2017).

An important subtlety is that the purely conceptual diagrams in Fig. 2 may obscure the fact that alternative molecular realizations may have different properties when viewed in the scale invariance setting. As an illustration, take the two realizations shown in Fig. 3 of the diagram in Fig. 2b. These two realizations differ in a fundamental way in regard to their scale invariance (FCD) properties. The biological mechanism in Fig. 3a exhibits FCD, but the one in Fig. 3b does not. To be more precise, we study the simplest ordinary differential equation (ODE) models for these processes, in which the concentrations of the input u and species x and y are described by scalar time-dependent quantities. Suppose that $(x(t), y(t))$ is any solution corresponding to the input $u(t)$, for the system described by Fig. 3a. Then, $(px(t), y(t))$ is a solution corresponding to the input $pu(t)$:

$$\dot{x} = \alpha u - \delta x \Rightarrow (\dot{px}) = \alpha(pu) - \delta(px)$$

Scale-Invariance in Biological Sensing, Fig. 2 Incoherent feedforward: (a) Input activates and intermediate species represses output; (b) Input represses and intermediate species activates output

Scale-Invariance in Biological Sensing, Fig. 3 Two realizations of the “input repressing output” motif in Fig. 2b: (a) Input inhibits the formation of output; (b) Input enhances the degradation of output

$$\dot{y} = \beta \frac{x}{u} - \gamma y \Rightarrow \dot{y} = \beta \frac{px}{pu} - \gamma y. \quad (1)$$

In particular, given a step input that jumps at time $t = 0$ and an initial state at time $t = 0$ that has been preadapted to the input $u(t)$ for $t < 0$ (that is, $x(0) = \alpha u_0 / \delta$, where u_0 is the value of u for $t < 0$), the solution is the same as when instead applying $pu(t)$ for $t > 0$ but starting from the respective pre-adapted state $p\alpha u_0 / \delta$. On the other hand, the FCD property *fails for the system in which the input enhances the degradation of output*, shown in Fig. 3b. Scaling states x by p does not work for this second system:

$$\begin{aligned} \dot{x} &= \alpha u - \delta x \\ \dot{y} &= \beta x - \gamma u y \end{aligned}$$

since $x \mapsto px$ and $u \mapsto pu$ do not leave the y equation invariant. Actually, one can prove that no possible equivariant group action on states is compatible with output invariance, which means that no possible symmetries are satisfied by the input/output behavior of this system. These issues are carefully discussed in Shoval et al. (2011), which carried out a systematic analysis of the FCD property and proved a necessary and sufficient characterization of FCD in terms of groups of symmetries acting on the system equations.

The above negative remarks notwithstanding, it has been observed that systems such as the one in Fig. 3b satisfy an *approximate* FCD property provided that the parameters β and γ are large enough so that a time-scale separation property holds. Multiple time scales, corresponding to slow and fast subsystems, are typically inherent in cellular systems. See Skataric et al. (2015) for a rigorous discussion of this topic.

Abstract

Scanning probe microscope (SPM) imaging control is to maintain a micromachined cantilever tip at the desired position with respect to the sample at nanoscale resolution while the probe is scanning the sample. The main objective is to drive the cantilever probe using piezoelectric actuators to follow the sample topography profile during the scanning process. Beyond conventional PI-feedback control, different approaches have been developed, ranging from robust control, adaptive control, to inversion-based feedforward-feedback control and iterative-based feedforward-feedback control. These

developments have demonstrated various levels of improvements over PI-control.

Scanning probe microscope · Tapping-mode imaging · Iterative learning control · Nanopositioning control · Adaptive multi-loop mode

Introduction

Scanning probe microscopy (SPM) has become a powerful tool for nanoscale imaging, property characterization, and patterning/fabrication. Particularly, based on the nature of the tip motion, SPM imaging can be categorized into static (i.e., contact) mode and dynamic (non-contact or tapping) mode. In contact mode, a micromachined cantilever probe with nanometer tip radius scans the sample line by line (usually in a raster pattern). During the scanning, the sample topography can be qualitatively captured using the deflection of the cantilever when the SPM z -axis scanner is kept at a constant height (i.e., the constant height contact mode). Or, more commonly, the topography can be quantified from the vertical z -axis displacement of the cantilever by maintaining the cantilever deflection closely around a pre-chosen set point through feedback control (i.e., the constant force contact mode). A major drawback of contact mode is that the sliding of the probe on the surface can result in sample deformation and damage. This issue can be mitigated through dynamic mode SPM imaging, by oscillating the cantilever around its resonance (with a piezoelectric actuator) during the scanning. The change of the oscillation amplitude or frequency, caused by the sample topography variation during the scanning, is then used as the feedback signal. The height of the cantilever is adjusted to maintain the oscillation amplitude or the frequency shift around the set point value, respectively, and the surface topography image is quantified from the z -axis displacement. Both types of imaging modes have

been broadly used in surface characterizations (see Fig. 1). Generally, contact mode is employed for samples with relatively high stiffness or those that are sensitive to impulse-like interaction (e.g., living cells), and dynamic mode such as tapping mode has been the de facto choice for relatively soft materials such as polymers.

As in other SPM operations, precision control of the probe position with respect to the sample is essential. Not only does the precision control of the probe-sample positioning ensure the imaging quality but also is required to avoid sample deformation and damage. Maintaining such a nanoscale positioning precision during high-speed imaging, however, becomes challenging due to the adverse effects of the vibrational dynamics and hysteresis of the piezoelectric actuators (Clayton et al. 2009), the complicated non-linear probe-sample interaction (in tapping-mode imaging), and the ultra-fragile surface of the sample (such as living cell) prone to deformation and damage. High-speed SPM imaging is needed to capture dynamic evolutions of the sample (such as the biological processes of living cells) – in addition to the improvement of imaging efficiency/throughput. These adverse effects in high-speed SPM imaging, although might be alleviated via hardware improvement (e.g., using piezoelectric actuators of higher bandwidth Shibata et al. 2010), need to be addressed via advanced control.

SPM Imaging Control

The control objective is to, during the imaging process, accurately track both the scanning trajectories in the lateral x - y - axes directions and the sample topography in the vertical z -axis direction. Although the desired lateral scanning trajectory (e.g., triangle trajectory – the default choice in almost all commercial SPM systems) is given a priori, the desired trajectory in z -axis – the sample topography profile on each scan line – is unknown a priori and tends to be largely irregular. This difference renders it more challenging to track the sample topography in the z -axis than the lateral scanning trajectory.

Lateral Scanning Control

In lateral scanning, the control issue mainly is to compensate for the vibrational dynamics and hysteresis effects of the piezoelectric actuators, coupled with environmental disturbances and system changes (e.g., the age of the piezoelectric actuators) (Clayton et al. 2009). Feedback control techniques such as PID control have been broadly used for their robustness against system variations, modeling error, and disturbances. PID control, currently widely employed in commercial SPM systems, is adequate for SPM imaging at relatively low speed and small range. However, the performance of PID deteriorates as the imaging speed increases, particularly at relatively large scan range. To enlarge the closed-loop bandwidth, robust control techniques have been developed (Sebastian and Salapaka 2005; Schitter et al. 2004). Alternatively, the adverse effects of creep, hysteresis, and vibrational dynamics in SPM piezo-positioning system can be quantitatively characterized and compensated for via model-based feedforward control, particularly the inversion-based feedforward control (Croft et al. 2001; Clayton et al. 2009). The robustness of the inversion-based feedforward approach can be enhanced by integrating the feedforward control to a feedback control loop (Schitter et al. 2004; Zou et al. 2004).

Further tracking improvement in lateral scanning has been witnessed through the development of iterative learning control (ILC) to SPM imaging applications (Tien et al. 2005). The repetitive nature of lateral scanning – with the entire desired trajectory known a priori – provides an ideal scenario for ILC application. For example, the following inversion-based iterative control (IIC) (Tien et al. 2005) has been shown to be effective to compensate for both the dynamics and hysteresis effects of piezoelectric actuators (Wu and Zou 2007).

$$u_{k+1}(j\omega) = u_k(j\omega) + \rho G^{-1}(j\omega) [y_d(j\omega) - y_k(j\omega)] \quad (1)$$

where “ $j\omega$ ” denotes the Fourier transform of the corresponding signal, $u_k(j\omega)$ and $y_k(j\omega)$ are the input and output signals in the k th iteration, $y_d(j\omega)$ is the desired trajectory, $G(j\omega)$ is the dynamics model of the piezoelectric actuator, and $\rho > 0$ is the iterative gain to be designed, respectively. As the system variation and the environment uncertainty in SPM operations are largely quasi-static (i.e., the input-output mapping of the system remains largely unchanged during each operation, even though the day-to-day variation can be significant), ILC avoids the performance-

robustness trade-off as that in usual feedback framework and attains both high performance and robustness (e.g., the quasi-static system changes can be accounted for via a couple of iterations right before the operation). The ILC approach has also been extended through a data-driven approach (Kim and Zou 2013; Wang and Zou 2015), by replacing and updating the a priori measured inverse model in Eq. (1) with the input-output data measured in the previous iteration, e.g., replace $G^{-1}(j\omega)$ with $u_k(j\omega)/y_k(j\omega)$ (Kim and Zou 2013), and, furthermore, with those measured data in past iterations (Wang and Zou 2015). Such an extension eliminates the modeling process and further enhances the tracking. Experimental results demonstrated superior tracking performance in large-range, high-speed tracking (Kim and Zou 2013; Wang and Zou 2015).

Efforts have also been made to increase the scanning speed through trajectory design, i.e., design non-raster, smooth scanning trajectory, to mitigate and remove the high-frequency components contained. Different scanning trajectories including cycloid, spiral, and lissajous patterns have been proposed (Mahmood and Moheimani 2009; Yong et al. 2010). Combining with advanced feedback control, lateral scanning speed can be increased at the cost of having a varying-speed scanning (e.g., nonuniform spatial sampling).

Vertical Sample Topography Tracking

Compare to the control of lateral scanning, tracking the sample topography in the vertical z -axis direction is much more challenging. Unlike in the lateral scanning, the sample topography – the desired trajectory to track – is, in general, unknown a priori, and sample topography tracking can be sensitive and disturbed by the probe-sample interaction force, particularly in tapping-mode imaging. Moreover, accuracy in topography tracking is more critical to both the imaging quality and preserving the sample (soft samples).

Traditionally, PID control has been commonly used in commercial SPM systems for z -axis topography tracking. As the scanning speed increases, H_∞ -based robust control and model

predictive control techniques have also been developed to improve the topography tracking (Quant et al. 2009; Rana et al. 2012). The effectiveness of these feedback control methods, however, is limited due to the adverse effects of the piezoelectric actuator becoming more severe in high-speed imaging, and the trade-off between the performance and the robustness requirement (resulting in a limited closed-loop bandwidth). Then, feedforward control has been augmented to the FB-loop in the feedforward-feedback (FF-FB) control configuration (see Fig. 2). The feedforward controller has been developed via approaches including the stable-inversion and the robust control, and the desired trajectory to be tracked has been approximated as the topography profile measured on the preceding scan line (Schitter et al. 2004). To further improve the topography tracking at higher scanning rate, ILC, particularly, the IIC technique has been extended and implemented online as the feedforward part of the FF-FB controller (Wu and Zou 2009). The basic idea is to repetitively image on the first line until the convergence is reached (usually within only 3 to 5 iterations), then continue on the rest of the scan lines without iteration. As having been analytically quantified and experimentally demonstrated, this online iteration scheme converges in practice as long as the convergence is attained faster than the line-to-line topography variations (Wu and Zou 2009). The ILC-based FF-FB control has also been further extended by improving the feedforward part with the modeling-free, data-driven ILC approach mentioned above (Ren and Zou 2014), or the feedback part with techniques such as model predictive control (Xie and Ren 2019).

Recent Trends

Recent efforts in control of SPM imaging have been focused on optimization of the imaging process, further increase of the imaging speed in large range scanning, high-speed dynamic mode imaging, non-conventional mode of imaging, and

combination of imaging with other surface characterization operations.

Optimization of SPM Imaging Process

First, attention has been steered towards the optimization of the imaging process itself. For example, the topography tracking error can be accounted for in the sample image generation to improve the quality. This concept – account of the tracking error in the topography quantification – has also been extended to adaptively tune/adjust the set point of the cantilever deflection (i.e., the probe-sample force) – instead of using a pre-chosen *fixed* value as in conventional SPM imaging. With this online tuning of the deflection set point, the probe-sample interaction force can be minimized, i.e., around the minimal value needed for maintaining a stable probe-sample contact (Ren and Zou 2014). This notion of adaptive deflection (force) tuning has also been extended to tapping-mode imaging, by

regulating not only the tapping amplitude, but also the mean value of the probe tapping, leading to a multi-loop FF-FB control approach (Zou et al. 2017). The efficacy of such an adaptive SPM imaging approach has been experimentally demonstrated (see Fig. 3). Also, to reduce the probe-sample force – critical in imaging soft samples, particularly live biological species, it has been proposed to adaptively adjust the scanning speed to accommodate the topography variation (Zhang et al. 2011), such that the sample deformation can be minimized while the overall imaging throughput can be improved (Ren and Zou 2018). Alternatively, the scanning pattern can also be designed to explore the sparsity of the sample – rather than scanning the entire imaging area, the total scanning might be reduced by only focusing around the features of interests (e.g., the DNA strands) (Andersson 2007), or scanning randomly-selected short-length pieces based on the compressed sensing concept. This

local-scan approach, however, requires that some priori knowledge of the sample pattern has been acquired, or rapid probe engagement and withdrawn can be attained (Wang and Zou 2018).

Simultaneous Topography Imaging and Property Mapping

Secondly, efforts have also been explored to combine topography imaging with mapping of other sample properties such as the nanomechanical properties of the sample (Li and Zou 2017; Li et al. 2019). This simultaneous imaging and mapping of the sample allows real-time correlation between the topography and other sample properties, needed particularly when the sample is undergoing dynamic evolution. The basic idea is to inject an excitation stimulus input (for the nanomechanical mapping) into the imaging feedback control loop and utilize Kalman filtering technique (Ruppert et al. 2016) to decouple and split the responses (Li and Zou 2017; Li et al. 2019). Aiming to broaden and expand the applications of SPM imaging, these efforts bring more control challenges and opportunities in emerging implementations (e.g., dynamic biological process).

Scheduling of Batch Plants

John M. Wassick
The Dow Chemical Company, Midland,
MI, USA

Abstract

For manufacturers operating batch plants, production scheduling is a critical and challenging problem. A thorough understanding of the problem and the variety of solutions approaches is needed to achieve a successful application. This entry will present a brief overview of batch operations and the state of the art of batch plant scheduling for nonexperts in the field.

Keywords

Dispatching rules · Optimization · Process networks · Production sequencing · Product wheel

Introduction

Batch plants, manufacturing operations composed of unit operations that operate in batch mode, are the primary manufacturing operations for the production of high margin products such as pharmaceuticals, specialty chemicals, and advanced materials. The scheduling of the sequence of operations over time has a significant impact on the overall performance of a batch plant (White 1989). The economic importance of batch plants, and the importance of scheduling for batch plants, has spawned a large body of research on the topic and a variety of commercial offerings.

The Nature of Batch Plants

In batch operations, the material transformation takes place in stages and the operation of each stage occurs over a specified time while the material remains in a particular unit operation performing that stage of production. (A familiar batch operation is baking a cake. Ingredients and their amounts, specified by a recipe, are combined and then subjected to a constant temperature over specified period of time to produce a cake.) A batch plant may have parallel units for some stages. Other stages may be operated in a continuous flow mode with a storage unit feeding the stage and another storage unit receiving the stage output. The path through the unit operations may be product dependent. Batch plants have highly diverse operational characteristics.

There are two broad categories of batch processes: (1) sequential where a batch moves from one stage to another without losing its identity and (2) networked where batches can be combined or split to feed downstream units (Mendez et al. 2006). Sequential processes can be further

classified as single stage, multi-stage, or multi-purpose.

The nature of a batch process and the different process structures can be explored by referring to the process depicted in Fig. 1 (Chu et al. 2013). As drawn, this batch plant operates as a multi-stage sequential process where a batch starts in raw material preparation stage (selected raw materials are loaded and then blended for a specified time), moves to the reaction stage with two parallel units (prepared raw materials plus additives react at a constant temperature for a specified period of time), moves to the finishing stage (intermediate product is subjected to a vacuum for a specified period of time to remove volatile by-products), and finally is processed in the drumming stage (finished product is packaged in drums). If finished product storage tanks were placed between finishing and drumming to allow the drumming stage to be scheduled independently of the first three stages, then the drumming operation would represent a single stage sequential process. If we further assume that for some finished products Reactor 1 produces a batch of precursor for Reactor 2 and that some products produced in the reactors bypass the finishing stage and go directly to drumming, then the underlying plant would be a multi-purpose sequential process. Finally, if intermediate storage tanks exist for storing multiple batches of the precursors produced by Reactor 1 and the contents of the tanks are drawn off to produce multiple, subsequent batches in both reactors then the underlying plant is a networked process.

Besides the general structure of a batch plant, the specific processing requirements,

resources needs, and process constraints have significant impact on the complexity of the scheduling problem. One important aspect is limited resources that are shared between different operations. The availability and capacity of shared resources place a severe constraint on the timing of competing operations. Another significant factor is intermediate storage between stages and the inventory policies that are enforced. Like shared resources, intermediate storage places hard constraints on the timing of upstream and downstream stages, especially when no storage is available. A third important constraint on scheduling is product transition policies that dictate what operations need to be performed to move from one product to another in a given stage. Such operations, sometimes called setups, might involve cleaning, or producing buffer batches to isolate the chemistry of one product from another. These operations involve costs and subtract from the productive use of the equipment so they have significant impact on the sequencing of products through the plant.

Production Scheduling of Batch Plants

Production scheduling in a batch plant involves three fundamental decisions: (1) determining the size of each batch in each stage, (2) assigning a batch to a processing unit in each stage, and (3) determining the sequence and timing of processing on each unit. These decisions are well illustrated by a graphical planning board or Gantt

Scheduling of Batch Plants, Fig. 1 Example batch plant (Solid lines represent material flows from limited inventory. Dashed lines represent material flow from unlimited inventory)

chart as shown in Fig. 2 (Chu et al. 2013). Personnel charged with creating and managing production schedules often rely on such a graphical tool to construct, analyze and report the schedule. Generally production schedules are determined using the information listed in Table 1.

The scope of the scheduling decisions is defined by the level of process detail considered in the scheduling problem. This idea can be examined by referring to Figs. 1 and 2. Such a Gantt chart could apply to a batch plant with four stages of production: raw material preparation, reaction, finishing, and drumming, with two parallel reactors in the reaction stage. If dedicated finished product storage exists with large enough capacity to cover the process lead time then one schedule could be confined to the first three stages of production and a different schedule applied to the drumming stage. The scope of the scheduling problem could be further reduced if raw material preparation only takes place just in time to load a reactor rather than execute as soon as possible. In this situation, the time for raw

material preparation could be added to the reactor batch time and the schedule would involve only the reactors and the finishing system with the raw material unit or units schedule implied by the reactor schedule. At a higher level still, the first three stages of production could be considered a production train and scheduling could then be reduced to planning campaigns of batches for each product over time with the detailed synchronization of the individual stages left to operations personnel. Obviously with each level of abstraction some efficiency in the schedule is lost and subsequently the opportunity to increase throughput of the plant.

In most batch plants a person with a title such as “production scheduler” is charged with the scheduling decisions. In general, the production scheduler is responsible for delivering a production schedule that meets customer orders on time and maintains finished product inventory while dealing with rush orders, late deliveries, equipment breakdowns and other contingencies. Generally schedulers develop and publish a schedule

Scheduling of Batch Plants, Fig. 2 Gantt chart of a production schedule

Scheduling of Batch Plants, Table 1 Information generally used to construct a production schedule

Scheduling information	Examples
Detailed production recipes	Batch times, processing rates, unit ratios, sequence dependencies
Equipment data	Capacities, availabilities, product suitability
Facility information	Shared resource availability and capacities, storage capacities
Production costs	Raw materials, utilities, setups, cleanings, manpower
Production targets	Inventory replenishments, customer orders with due dates
Current process status	Current inventories, operations in progress, schedule items fixed in future time

to manufacturing on a regular basis (e.g., every 2 days, once a week, etc.) and then monitor ongoing circumstances (e.g., actual production vs. plan, new demand, etc.) to determine if minor adjustments to the schedule are needed or if a complete new schedule needs to be published. The construction of a schedule can be an iterative process involving negotiations with manufacturing, supply chain, sales, maintenance and logistics. The tools available to the production scheduler can have a significant impact on the quality of schedules they produce.

It is evident from the description above that production scheduling of batch plants is really carried out as an exercise in rescheduling in response to disturbances identified through feedback from the process and market. Under these circumstances production scheduling serves as a form of high level feedback control of the process. In this regard the manipulated variables are the production amounts for each product and the controlled variables are the inventory levels and customer service levels for each product. A scheduling problem can be converted to a state-space formulation and compared to model predictive control (Subramanian et al. 2012).

Solution Approaches

The solution approaches applied to scheduling batch plants cover a wide spectrum of sophistication. A very simple form is nothing more than a sequence of batches maintained on a white board in the plant control room. A level above this would be the use of custom spreadsheets for arranging batches chronologically and computing finished product inventory. Another step up is the use of a manually manipulated Gantt chart as illustrated in Fig. 2, possibly pre-populated by an automated planning application that determines the volume to be produced across the units of production while leaving the detailed sequencing and timing decisions to the production scheduler. The highest level of sophistication involves an automatically generated schedule with the application retrieving all the necessary data from the

appropriate business databases and plant control system.

Regardless of the level of sophistication, all solution approaches rely on two fundamental components for developing a schedule. One is the modeling paradigm used to represent the physical system in a more abstract way. The primary components are: material balances in terms of batches or units of measure (e.g., pounds), and timing information as either precedence-based describing the order of operations or time grid-based describing the instant at which any operation takes place. Time can either be described by a continuous representation or divided into discrete increments. Within these two aspects of the modeling framework, significant freedom exists to describe the scheduling problem. The second fundamental component is the solution method used to generate the schedule. Each method has its strengths; therefore solutions combining methods are also used. The essential problem is to produce the information needed to draw the Gantt chart in Fig. 2 given the information in Table 1.

Product Wheel

While the primary objective of production scheduling is to meet customer orders while managing finished product inventory, other operational issues need to be managed, such as minimizing product transition costs, minimizing variability in manufacturing operations, keeping the scheduling process simple, and balancing the tradeoff between production lead times, inventory, and transition losses. The product wheel is a practical approach widely used in industry to address these competing issues. A product wheel is a regular repeating sequence of products made on a specific unit operation or an entire production process. A product wheel is typically depicted as a pie chart as shown in Fig. 3. Segments of the pie, called spokes of the wheel, represent a production campaign of a particular product. The size of the spoke represents the length of the campaign relative to the overall duration, or cycle time, of the wheel.

A product wheel has specific design parameters to address various operations objectives. The sequences is fixed and optimized for minimum

Scheduling of Batch Plants, Fig. 3 Product wheel

transition costs. The overall cycle time is fixed and optimized to balance lead time and inventory costs. The campaign size or spokes for each product are sized to match average demand for each product. The fixed pattern of the product wheel provides manufacturing with a predictable operational rhythm and the production scheduler with a very structured decision framework. Refer to King and King (2013) for a complete treatment of product wheels.

In practice, the duration of a campaign for a given product will vary from cycle to cycle as it will be sized to replenish any inventory consumed in the previous cycle. Low volume products may not be made on every cycle, although they will have a fixed location in the sequence. This same approach applies to make-to-order products that are not inventoried but produced to fill specific orders. Thus, in some cases a product wheel may be composed of several different but repeating cycles.

Dispatching Rules Used in Discrete Manufacturing

Batch processes are closely related to discrete manufacturing. Batches processed on a unit are analogous to jobs processed on a machine. Much of the literature on machine scheduling has focused on the analysis of the specifics encountered in general classes of problems such as single machines, parallel machines, flow shops and job shops, and developing constructive scheduling rules where a schedule is built up by adding one job at a time (Blackstone et al. 1982). Under certain circumstances these rules used for machine scheduling can be applied to

scheduling batch plants. This allows one to take advantage of a great body of literature, and at times, very simple scheduling rules that have proven optimality or worst case performance limits.

Consider again the batch process referred to in Fig. 1 which has two parallel reactors. The two reactors can be modeled as a single stage process and scheduled like parallel machines using the simple *shortest processing time first* (SPT) rule if the following circumstances hold: (1) raw material preparation can be included in the batch time of reactors, (2) significant storage exists between the reactors and finishing to essentially isolate the two stages, (3) product specific batch times are identical for both reactors, (4) the number of batches of each product is given (perhaps the result of an inventory policy for make to stock products), and (5) the objective is to minimize the total completion time for all batches. The SPT rule is simply to select, whenever a reactor is free, the batch with the shortest processing time from those yet to be processed. This can be proven to produce an optimal schedule for the given conditions.

Another simple dispatching rule to mention is the *earliest due date first* (EDD) rule. This rule is designed for single stage processes without parallel units where each batch has an associated due date. The rule simply orders the batches in increasing order of their due dates to minimize the maximum lateness of all orders.

The conditions needed for the SPT rule or the EDD rule to produce an optimal schedule can be quite restrictive when considering batch processes, however these rules and others found in the machine scheduling literature (Baker and Trietsch 2009) can still produce a good initial schedule even in cases where optimality conditions are not satisfied. Once generated, the schedule can be improved by manual manipulation of the Gantt chart or the application of improvement heuristics.

Improvement Heuristics

Improvement heuristics try to improve the current schedule by searching for alternative solutions either in the neighborhood of the current schedule

or by broadly exploring the solution space. The behavior of these algorithms is determined by tuning parameters that balance the use of the two search techniques and the underlying algorithm that performs the search. Improvement heuristics generally have the following basic procedure:

- Step 1: Initialize – determine a starting schedule
- Step 2: Generate alternatives – build modifications to the current schedule
- Step 3: Check for improvements in modified schedule – if no improvement is found return to Step 2 otherwise proceed to Step 4
- Step 4: Check for termination – terminate the algorithm if the number of iterations is exceeded or minimal improvement is obtained.

Many improvement heuristics are inspired by processes found in nature. Two of the more popular heuristics are simulated annealing which mimics the crystal formation during the cooling process of dense matter (Ryu et al. 2001) and genetic algorithms that mimic the evolution of a species over time (Löhl et al. 1988). A key aspect of improvement heuristics is the representation of the schedule in context of the algorithm used. For problems with complicated constraints this becomes a challenge. Nevertheless, when tuned properly and used where they fit the problem, improvement heuristics can produce very good schedules quickly.

Tree Search Methods

The scheduling solutions considered so far have taken a relatively simple view of a batch process as a single stage process or a flow shop. In situations where a batch plant involves shared resources, complicated transition rules or is a process network, tree search methods are better suited because they can deal with a large number of degrees of freedom and many types of constraints. Tree search methods rely on representing alternative schedules as the final nodes in a tree where intermediate nodes represent partial solutions of the schedule. To be practical, these methods must be able to effectively search through the tree while pruning non promising branches (see Fig. 4). Three of the most popular techniques are

Scheduling of Batch Plants, Fig. 4 Trimming the solution tree

mathematical programming, constraint programming, and beam search.

Mathematical programming solution techniques for scheduling generally convert the problem to a mixed integer linear programming (MILP) formulation where branching at nodes of the tree represent alternative values of the integer or binary variables. The tree is searched by a branch-and-bound algorithm which eliminates a node and the branch that emanates from it if the lower bound of the objective function represented by the terminal nodes of the branch is larger than the current best schedule. The MILP formulation can be stated generically as

$$\begin{aligned} \min \quad & z = cx + fy \\ \text{s.t.} \quad & Ax + By \geq b \\ & x \in \mathbb{R}_+^n, y \in \{0, 1\}^p \end{aligned}$$

where c , f , b are vector of constants, A and B are matrices of constants, and the solution is defined by the vector variables x and y . A key feature of using mathematical programming is to represent the relationships implied in Table 1 and Fig. 1 in terms of algebraic descriptions. The advantage of this approach is that a proven optimal solution exists for a problem stated this way. This provides the means to assess the quality of the solution and the impact of implementing the solution. The drawback of this approach is that since binary variables are used to represent the assignment of a batch to a processing unit, and the sequence and timing of processing on each unit, their number grows rapidly with the number of units and the length of the scheduling horizon. However, the performance of modern computing hardware and commercial solvers for MILP problems has allowed industrial size problems to be tackled.

A large variety of modeling paradigms have been developed to produce a MILP solution (Floudas and Lin 2004; Mendez et al. 2006). They address both sequential and networked processes using continuous time or discrete time representations. For sequential processes, time slot approaches have been developed. For networked processes, the resource task network and the state task network have been investigated by many researchers and have been used in industrial applications.

Constraint programming (CP) formulates a problem by writing constraints; but unlike the MILP method, the CP method stresses the feasibility of solutions rather than optimality. Another important difference is that constraints in the CP method do not have to be formulated as algebraic relationships but can be a more general form, thus making it easier in CP to represent complicated constraints. CP processes the constraints sequentially to reduce the space of possible solutions. At each node in the tree, CP processes one constraint after another, reducing the search space at each constraint. Being much newer than mathematical programming, constraint programming has a smaller body of literature to review but excellent performance has been reported in the literature (Baptiste et al. 2001).

In the beam search method, the branch-and-bound algorithm is modified to only evaluate the most promising nodes at any given level of the search tree (Ow and Morton 1988). The number of nodes evaluated is called the beam width and it is a key tuning parameter of the method. Another important element of the method is the technique used to retain nodes for complete evaluation. The technique must balance speed versus thorough evaluation to keep the method practical without discarding promising nodes. The beam search method applied to scheduling has been investigated by many authors (Sabuncuoglu and Bayiz 1999).

Simulation

The simulation approach to scheduling batch plants relies on representing the plant and the relationships inferred by Table 1 in a computer program whose algorithms recreate the behavior

of the plant when executed. Generally, the simulators used for batch operations apply discrete event simulation (DES) where entities that have attributes like size, due date, priority, etc. are operated on by activities for a specified duration. Fundamental to DES are the use of queues to hold entities until conditions in the simulation allow them to proceed to their next activity. Time in a DES does not proceed in a continuous manner but rather advances when activities occur. Simulation has the advantage of being able to describe processes and operating policies of arbitrary complexity and model variability in the process operation. Simulators can be used to evaluate manually created schedules or can be combined with optimization and heuristics to produce schedules by simulation-based optimization (Pegden 2011).

An alternative to DES for batch scheduling is the use of multi-agent simulators which are composed of semiautonomous agents assigned to represent the operation of the process and the associated decision making. Each agent has a local goal and communicates with other agents to accomplish it. Like DES, multi-agent simulators are capable of describing very complicated processes. A production schedule can be built through negotiations between agents (Chu et al. 2013).

Selecting a Solution Approach

The selection of the approach for a given batch plant should be value-based, balancing improved revenue with long term cost of ownership by considering such factors as the technical competency of the production scheduler, the expected capacity utilization of the plant, the operational complexity of the plant, and the cost to maintain the scheduling application. The key is to obtain the least complicated solution by reducing the scheduling problem to the highest level of abstraction and by using the simplest solution method that provides an effective schedule. See Harjunkski et al. (2013) and Pinedo (2008) for a survey of methods and recommendations for their practical application.

Summary and Future Directions

While there are a great variety of solution methods for scheduling, there are still promising research areas to be investigated. The recent introduction of sophisticated, object oriented process control systems with ties to enterprise management systems sets the stage for the development of automatic, real time scheduling. It is here that the principles of feedback control can be applied to batch plant scheduling. Pursuit of this goal will require continued development of fast, adaptive scheduling methods, real time assessment techniques of schedule performance, and tight integration of scheduling with the process control.

Sensor Drift Rejection in X-Ray Microscopy: A Robust Optimal Control Approach

Sheikh Mashrafi¹, Curt Preissner¹, and Srinivasa Salapaka²

¹Argonne National Laboratory, Lemont, IL, USA

²University of Illinois at Urbana-Champaign, Urbana, IL, USA

Abstract

High-resolution x-ray imaging requires the relative motion between the zone-plate optics and sample stages to accurately track a reference trajectory with large temporal bandwidth and high positioning resolution. Recent advances in feedback control designs have enabled large tracking bandwidth, high positioning resolution, disturbance

rejection, noise attenuation, and robustness to unmodeled plant dynamics. However, these efforts have been impeded by sensor drifts, which are not adequately addressed by existing designs. Especially since high-resolution x-ray imaging experiments are typically of long duration, the uncompensated effects of drifts result in imaging artifacts and substantial degradation in achievable spatial image resolution. In this entry, a method is presented for countering sensor drift in real-time through drift measurements and incorporating them in an optimal control architecture.

Keywords

Drift measurement · Real-time compensation

Introduction

X-ray microscopes provide critical advantages over optical counterparts since they achieve higher image resolutions on the order of nanometers due to their shorter wavelengths and enable imaging the internal structure of samples since they penetrate matter far easier than visible light. In scanning transmission x-ray microscopy (STXM), x-rays are produced by passing a high-energy electron beam through a periodic array of magnets, where the Lorentz force causes undulations, as shown in Fig. 1. These undulations elicit the production of synchrotron radiation, an intense beam of x-ray light. This beam, after being filtered through a monochromator, which selects a narrow bandwidth around a chosen frequency, is focused on the sample by appropriately positioning the zone-plate optics stage. This focused x-ray spot is then scanned along a predefined trajectory to cover a target region of the sample. The high-energy x-ray photons interact with the sample molecules and are diffracted in various directions as they pass through the sample, which are then detected downstream. A two-/three-dimensional image of the scanned sample is reconstructed from the recorded diffraction intensity data.

The image resolution is dependent not only on the quality of the x-ray beam but the precision of the relative motion between optics stage and sample stage. In Mashrafi et al. (2017), authors present a robust optimal control framework for the fine positioning of zone-plate optics stages, which was demonstrated on x-ray microscopes at Advanced Photon Source (APS) at Argonne National Laboratory (ANL). These experiments demonstrated reduction in scanning time by over four orders of magnitude, when compared to existing designs. This control-design framework for high-resolution, high-bandwidth, and robust positioning and tracking is well poised to remove positioning as a bottleneck for achieving high image resolution.

However, this framework relies heavily on how precisely the position of the moving optics stages are known with respect to the global reference frame. The high-resolution laser interferometric sensors are a great choice for implementing the feedback laws, except for one important limitation. The metal alloy fixtures that hold the sensor drift by hundreds of nanometers are due to the cyclic temperature changes, especially in long imaging experiments that can last many hours. For instance, temperature variations of about 0.6°C in a day can lead to a drift over 500 nm. These drifts are significant since the required positioning resolutions are only on the order of few nanometers. Since there is no way to distinguish between the actual motion of the scanning stage and the sensor drift, the control system does not even recognize the drift and fails to compensate for it. This entry presents a method to counteract the sensor drift.

Figure 2 illustrates the effect of sensor drift on position measurements of an optics stage. Such drift effects are present for the sample stage too; here we do not explicitly discuss its design since the framework presented for the optics stage directly extends to the sample stage. If there were no drift, and sensors were ideal, then the changes in the stage displacement y relative to the reference base are identical to the changes in the sensor measurement y_m ; however these are not the same when due to thermal

Sensor Drift Rejection in X-Ray Microscopy: A Robust Optimal Control

Approach, Fig. 1 A schematic diagram of the scanning transmission x-ray microscopy

drift of the sensor fixtures, the sensor head itself drifts by a distance d . The existing literature covers primarily image post-processing methods such as using linear and nonlinear drift model to detrend drift effects or filtering and averaging over multiple exposures to increase signal to noise ratio (Beckers et al. 2013). These methods do not address the thermal drift of sensor in real time and result in images where it is not easy to distinguish artifacts from true features in the images.

Drift Compensation Through Feedback Control

In the proposed concept, we add a sensor that measures the relative distance between a reference base and the sensor fixture, which allows for estimating drift of the primary sensor (sensor-1) and compensating for the drift effects. Figure 2 demonstrates the scheme where the optics-stage displacement y_m is measured with sensor-1 and its drift d is measured with sensor-2. Here the sensor-2 measures the motion of the sensor fixture to which sensor-1 is attached with respect to a fixed reference base and therefore gives a measure of the drift d . For nonideal sensors, the differential measurements about operating points are given by $y_m = y + n$ and $y_2 = d + n_d$, where n and n_d are the measurement noises in the two sensors. The measurement y_2 is incorporated in the optimal control design, whose objective is to counter the effects of the drift d .

Figure 3 represents the resulting closed-loop nanopositioning system. In this figure, G

Sensor Drift Rejection in X-Ray Microscopy: A Robust Optimal Control Approach, Fig. 2 Optics-stage measurement system. Primary sensor (sensor-1) drifts due to thermal drift of sensor fixture. Another sensor is added to detect this drift

Sensor Drift Rejection in X-Ray Microscopy: A Robust Optimal Control Approach, Fig. 3 Transfer function block diagram for the h-infinity minimization problem

represents the transfer function of the scanner which comprises the positioning flexure stage, the actuating, and the sensing components of the positioning system. Here y, u, r , and d represent the stage displacement, the input given to the actuator, the reference to be tracked, and the drift; n and n_d denote sensors' noise, and $y_m = y + n$ and $y_2 = d + n_d$ are the corresponding measurements. The main objective for the design

of the feedback control transfer function K is to make the tracking error small (how small is determined by the resolution requirement) over as large a bandwidth as possible while accounting for modeling uncertainties. The tracking error is given by $e = r - y - d = S(r - d) + T(n + n_d)$, where $S = 1 / (1 + G K)$ and $T = 1 - S$ are the sensitivity and the complementary sensitivity transfer functions. For good noise attenuation, the controller K needs to be such that $T \approx 1$ within the tracking bandwidth and small in high frequencies where measurement noise n and n_d are predominant. Similarly for drift compensation, S should be small over the desired tracking bandwidth and in low frequencies where drift d is predominant. Also, low values of the peak in the magnitude plot of sensitivity S ensures robustness to modeling uncertainties.

The robust optimal control theory provides an apt framework for incorporating these objectives. In this framework, it is possible to determine if a set of design specifications are feasible, and when feasible the control law K is obtained by posing and solving an optimization problem using easily accessible software routines (e.g., hinfsvy in Matlab). The main advantage of using this optimization framework is that it incorporates performance objectives directly into its cost function. This eliminates the tedious task of tuning gains (in trial-and-hit manner) as in the proportional-integral-derivative (PID) control designs, where even the exhaustively tuned gains may fail to yield acceptable performance. In our context, the optimal control algorithm K is obtained by solving the following minimization problem, $\min_{stab.K} \|T_{wz}\|_\infty$, where, T_{wz} is the closed-loop matrix transfer function from exogenous inputs $w = [r - d \ n \ n_d]$ to regulated outputs $z = [z_s \ z_u \ z_r]$. Here the weighted tracking error $z_s = W_s (r - y - d)$, weighted stage displacement $z_t = W_t y$, and weighted control effort $z_u = W_u u$ are the output signals that need to be made small; accordingly W_s is designed to be high over the desired tracking bandwidth, W_t is high over the frequency range where sensor noise is dominant, and W_u is made high in those frequency ranges where the control effort needs to be small.

Experimental Setup and Results

Figure 4 illustrates the experimental setup. Here laser interferometric sensor is used to measure the displacements, where mirrors are fitted on the target surfaces and on the back of each sensor for reflecting the laser beam coming from the sensors. Such sensor shown as [7] with corresponding mirror [6] is used to measure the position of the piezo actuated [4] Al-alloy target [5], and sensor [8] measures the drift of the sensor [7]. Sensor [7] is positioned at one end of Al-alloy bar [9] (sensor fixture), which is attached on an Al-alloy post [11]. Sensor [8] is attached on another Al-alloy post. To replicate the sensor thermal drift, two heat sheets [10] were attached on both surfaces of the Al-alloy bar [9] and were turned on/off for certain time periods. The sensor measurements were used for the feedback which were implemented on a field-programmable gate array-based digital signal processor running at 40 MHz.

To determine the piezo actuator and stage dynamics, a band-limited uniform white noise with amplitude 1500 nm was given as input to the actuator, and the corresponding displacement was measured. A 18th order model G was fit to

Sensor Drift Rejection in X-Ray Microscopy: A Robust Optimal Control Approach, Fig. 4 Setup for sensor drift rejection

Sensor Drift Rejection in X-Ray Microscopy: A Robust Optimal Control Approach, Fig. 5 Bode plots of (a) the positioning system G and the designed controller K ;

(b), (c) simulated and experimental sensitivity (S) and complementary sensitivity (T) maps

the nonparametric frequency response function, which was estimated from the time-domain input-output data (Fig. 5a). The first resonance peak of the actuator is around 800 Hz. Accordingly, the optimal control problem presented in the previous section was solved to obtain K shown in Fig. 5a; the resulting sensitivity S and complementary sensitivity T transfer functions are shown in Fig. 5b, c.

To replicate a 24-h thermal cycle of the APS beamline at ANL, the heat sheets were turned on for 10 min. Data was collected for 30 min to let the setup cool down to ambient temperature. The open-loop (OL) response of a sinusoidal signal with amplitude 1000 nm and frequency 8 Hz is shown in Fig. 6a. It does not distinguish sensor

drift (d_{OL} , (Fig. 6c)) from the actuator motion, and, consequently, the tracking error $e = r - y$ (Fig. 6b) is quite large and mimics the sensor drift. The closed-loop tracking error on the other hand is only about 2% of the input amplitude, of which 1% is due to the sensor noise.

The positioning resolution of the actuator in open-loop (no knowledge of sensor drift) and in closed-loop (with knowledge of sensor drift) was calculated by giving a zero reference signal, where the actuator is solely driven by external disturbance and noise. Respective noise histograms of the measured displacements in Fig. 7 demonstrate an improvement of over 180% in 3σ -resolution – from 35.6 nm in open-loop to 3.8 nm in the closed-loop.

Sensor Drift Rejection in X-Ray Microscopy: A Robust Optimal Control Approach, Fig. 6 Open- (OL) and closed-loop (CL) tracking results. The control design achieves much better tracking as seen in (a), (b); the sensor drift is seen in (c)

Sensor Drift Rejection in X-Ray Microscopy: A Robust Optimal Control Approach, Fig. 7

Resolution experimental results. Histograms of open-loop and closed-loop responses to external disturbances and noise

Summary

To counter sensor drift, a key limitation of x-ray imaging resolution, an optimal control scheme is presented, which designs a feedback law that uses drift measurements to compensate for the drift

effects. The experimental tracking results demonstrate practical elimination of the drift effects with the design and substantial reduction of over 180% in positioning resolution. This design will significantly improve x-ray microscopy in terms of spatial resolution and quality of images.

Simulation of Hybrid Dynamic Systems

Pieter J. Mosterman, Akshay Rajhans, Anastasia Mavrommati, and Roberto G. Valenti
Advanced Research and Technology Office, The MathWorks, Inc., Natick, MA, USA

Abstract

Hybrid dynamic systems combine continuous and discrete behavior. An overview of semantic domains of dynamic behavior is presented in terms of the evolution domain, the value domain, and the execution domain. Simulation

of piecewise continuous behavior interspersed with discontinuities is investigated in detail and illustrated by an example that motivates the use of simulation support for hyperdense time as an evolution domain. Engineered systems are characterized by combinations of compute elements, network connectivity, sensors and actuators, and a physical component. The various different elements benefit from modeling formalisms based on various semantic domains. Efficient execution is achieved by a combination of time-driven and event-driven execution engines.

Introduction

Hybrid dynamic systems combine continuous and discrete dynamics. In the literature, hybrid dynamic systems are often referred to simply as hybrid systems where system is to be taken as a mathematical system (as opposed to a physical system). Hybrid systems as a term, however, are also used to refer to systems such as a hybrid powertrain where a combustion engine and electric motor connect to the driveline. Therefore, to avoid confusion, the term hybrid dynamic systems is used.

Hybrid dynamic systems enable a selective choice in how to represent modeled phenomena. Modeling a system under study by hybrid dynamics allows improved efficiency in terms of simulation. Moreover, the ability to include behavior in a coarse sense prevents the need for detailed parameter knowledge. For example, when an electrical switch is opened, its current flow does not fall to 0 instantaneously, but the opening creates a quickly decreasing contact area that results in a quickly decreasing change in current. Moreover, a quickly increasing air gap may support a brief moment of current flow with a corresponding spark. The details of these effects

(the properties of the contact area and the air gap as they change during a brief period of time) may be unknown and difficult to measure while being irrelevant to the overall behavior of interest (the current changes to 0). Other examples of physical components that may be well modeled by discrete on/off type behavior include diodes, valves, latches, clutches, relays, and so forth. Likewise, components that effect quick changes compared to the overall behavior of interest such as an analog to digital converter may be modeled by discontinuous change in their behavior.

Even though systems that include components with on/off or more generally discontinuous behavior may be intuitively modeled as hybrid dynamic systems (e.g., an antilock braking system, a rectifier circuit, an overflowing tank), a system under study is not intrinsically a hybrid dynamic system. A model is a chosen representation of a system under study depending on a specific purpose. For example, to achieve real-time simulation, a model that abstracts fast temporal behavior into discontinuities oftentimes is preferred. However, to gain insight in the physics of a system, it is conceptually preferred to capture fast behavior in detail (Breedveld 1996).

A key aspect of being a representation is that a model must be simpler than the system under study. Thus, a perfect copy would not be considered a model. This notion may be confounded with the model being “wrong,” yet if the model serves its purpose, it helps solve a problem, it is in fact “right.” The quality of the model reflects in its efficiency to solve the problem. Combining continuous dynamics with discrete dynamics provides flexibility in modeling to include the detail necessary but no more (conform the principle of parsimony or Occam’s razor).

Models of hybrid dynamic systems can be studied and leveraged in multiple ways, for example, formal property proving to guarantee the absence of design errors or automatic generation of embedded code. The focus of this entry, however, is on numerical simulation of such models, that is, given a hybrid system model and the initial conditions, numerically simulating the execution of the dynamics on a computer. Such an execution of hybrid dynamic systems requires

support for intricacies that bring to bear a unique set of challenges beyond the execution of continuous and discrete dynamics alone. In the proceeding, a number of motivating examples are presented to introduce various different forms of hybrid dynamic systems. Next, a range of semantic domains for dynamic systems and their execution semantics are introduced. The class of piecewise continuous systems is then discussed in detail as it embodies the broadest range of behaviors specific to hybrid dynamic systems. Next, the utility of the various different semantic domains in multiparadigm modeling is sketched followed by a discussion of execution engines to achieve efficient behavior generation. Finally, conclusions and open challenges are presented.

Motivating Examples

Examples of hybrid dynamic systems often used in the literature include a thermostat, a bouncing ball, and a freewheeling diode. Each of these allows concentrating on a particular aspect of hybrid behavior, namely, a discontinuous forcing function, state reinitialization, and event iteration, respectively.

Switched Control: A Thermostat

Switched control is a popular approach, for example, for tackling nonlinear system behavior. Piecewise linearization by approximating or abstracting the nonlinear behavior using a number of different modes of linear behavior allows synthesis methods to find control laws in each of the modes. Switching logic then selects

Simulation of Hybrid Dynamic Systems, Fig. 1
Thermostat model. © The MathWorks, Inc.

Simulation of Hybrid Dynamic Systems, Fig. 2 Combining asymptotically stable behavior leads to unstable behavior. © The MathWorks, Inc.

the corresponding mode as the system under control (the process or plant) evolves.

Another example is a thermostat that employs bang-bang control. Here, the actuation is at its maximum (maximum heating) or its minimum (no heating). Figure 1 shows a hybrid dynamic system model of a thermostat as a finite state machine with a differential equation that models the behavior in each discrete state. The thermal behavior of the room is represented by the differential equation $\dot{x} = Ax + u$ with x being the temperature and u the heating control input. The heating u is active or not, depending on the state. When the temperature falls below a minimum ($x \leq \min$), the heating turns on, and when the temperature exceeds a maximum ($x \geq \max$), the heating turns off.

From a simulation perspective, there are two important considerations: (i) does the model always remain in one of the states for a duration of time (i.e., is $\max > \min$) and (ii) is it necessary to reset the numerical solver that generates behavior for the differential equations? The second concern depends on the solver type, where a multistep solver exploits computed values of previous time steps and assumes a certain order of continuity between time steps (Cellier and Kofman 2006).

While the simulation considerations are relatively straightforward, from a control perspective, hybrid behavior may evidence problematic behavior. For example, Fig. 2 shows two asymptotically stable behaviors, one on the left-hand side and one in the center. When switched control selects the behavior in the top-left quadrant of the center behavior to produce the combined

Simulation of Hybrid Dynamic Systems,

Fig. 3 Bouncing ball model. © The MathWorks, Inc.

behavior on the right-hand side, the resultant behavior becomes unstable. Issues of stability, reachability, nondeterminism, and so forth are particularly difficult in case of hybrid dynamic systems but beyond the scope of the simulation focus.

State Reinitialization: A Bouncing Ball

A key behavior to support in simulation of hybrid dynamic systems is the reinitialization of states in differential equations (the continuous state). Figure 3 shows a model of a bouncing ball, a much studied example of this behavior. The differential equations that are active in the discrete state capture the velocity of the ball, v , as subject to the gravitational acceleration, g . When the position of the ball, x , falls below 0 (to represent the floor level), an elastic collision sets the velocity of the ball to a new value v^+ based on the velocity upon collision and a restitution coefficient ε .

The discontinuity as introduced by reinitializing the continuous state requires the same numerical solver considerations as the discontinuity introduced by switching input of the thermostat problem. The bouncing ball, however, highlights detecting the collision event as a challenge. Consider ε to be positive but less than 1. As the ball bounces repeatedly, the maximum height of each bounce progressively decreases. When this

maximum height becomes less than the numerical tolerance set to detect whether $x \leq 0$, the transition is always enabled. At this point, further simulation becomes ill defined.

Event Iteration: A Freewheeling Diode

A key feature of hybrid dynamic systems is the occurrence of a sequence of discrete state changes with no duration of continuous-time behavior in between. Figure 4a shows an electrical circuit with two elements modeled with discontinuous behavior: (i) the switch, S , enforces a 0 voltage drop when closed and a 0 current flow when open, and (ii) the diode, D , enforces a 0 voltage drop when on and a 0 current flow when off. When the switch is closed, the battery, B , supplies a voltage that builds up a flux in the inductor, L . The corresponding current flow creates a voltage drop across the resistor, R , and when less than the battery voltage, this results in a positive voltage across the diode in its off state.

Figure 4b shows a model of the electrical circuit as a state machine with three parts. At the top, the equations for the inductor are shown where the inductor flux, p , builds up based on the voltage drop, V_D , across the parallel branch. The current through the switch, I_S , minus the current through the diode, I_D , is the inductor current and directly represented as the flux per inductance, $\frac{p}{L}$.

Below the equations are two state machines, one to model the behavior of the switch and one for the diode. The switch is opened when time, t , reaches 1. At the point in time when the condition $t \geq 1$ becomes true, the switch changes its behavior from allowing arbitrary current with 0 voltage drop to allowing an arbitrary voltage with 0 current flow. Given that the diode also enforces 0 current flow, the inductor current is forced to 0, which requires an instantaneous discharge of its flux, p .

Because of the discontinuous change in flux, according to the differential equation $V_D = \dot{p}$, a negative voltage spike across the parallel branch would occur. This voltage, however, enables the $V_D \geq 0$ condition (notice the orientation of the diode with its positive port connected to ground), and the diode comes on such that the diode

provides the inductor current instead of forcing it to 0.

In addition to the complexity of handling such event sequences, hybrid dynamic system simulation must handle impulsive behavior such as the voltage spike. Moreover, the simulation must be able to compute discontinuous changes in continuous state from a system of equations (i.e., the reinitialization value is not explicitly provided as an assignment).

Semantic Domains

Given the notion that hybrid dynamic systems combine continuous and discrete behavior, it is instructive to investigate in more detail the semantic domains used in modeling and simulation. To establish a fundamental structure of these semantic domains, note that the dynamic nature of the systems implies there is a domain on which behavior evolves. A behavior, β , is then a mapping of an evolution to values where a hybrid dynamic system can be thought of as a partial function with the evolution domain, $\mathcal{E}$, as its domain and the value domain, $\mathcal{V}$, as its codomain

$$\beta : \mathcal{E} \mapsto \mathcal{V} \quad (1)$$

In addition to the evolution and value domains, dynamic systems often allow value changes at specific instances only. These instances form the execution domain, $\mathcal{X}$.

Integer Evolution Behavior

In its basic form, an evolution domain comprises a set of linearly ordered instances. This can be represented by the natural numbers, $\mathbb{N}$, even if the metric notion may not be relevant. For example, program code such as C, Java, and MATLAB® (MathWorks® 2019), when single threaded, follows a linear sequence of operations that can be indexed by integers. Execution of each operation follows completion of the previous operation, and so a program counter progresses along the integers without the need for independent dynamic scheduling. The discrete evolution domain is depicted in Fig. 5a by a

dashed horizontal axis, while the execution ordering is represented by squared arrows between consecutive execution instances. The solid vertical arrow representing the value domain captures the continuous values of computational operations. The solid circles depict values computed at discrete execution instances. It should be acknowledged that computational operations approximate continuous values by floating point representations, and so the domain is not truly continuous. In the value domain, this distinction is not important to the discussion.

Time is an evolution domain that is integral to hybrid dynamic systems. In computational implementations, it is often preferred to discretize time in periodic steps of equal size, the sample time. Figure 5b depicts time as a discrete evolution domain such that it can be specified by difference equations or synchronous data flow (Benveniste et al. 2003). Note that the base rate of the scheduler has a sample time that is represented by the vertical lines, but not every base rate sample hit

corresponds to the execution of an operation. For example, in case of a system with operations that have a sample time of 2 s and operations that have a sample time of 3 s, the base rate has a sample time of 1 s (the greatest common divisor). At 5 s, the base rate has a sample hit but neither of the other sample times does. As in programming code, the value domain is continuous.

Because of the integer nature of the execution, in case there is no real-time execution requirement, the scheduler may operate similar to the execution of program code and progress along an integer schedule. The sample times of operations are harmonics of the base rate and, therefore, execute at integer multiples of the execution index. In case real-time behavior is required, each integer advance is invoked based on a periodic interrupt from the compute platform.

Similar in execution but different in behavior is the discrete-time evolution domain shown in Fig. 5c. Here, the value of a behavior changes at a periodic rate, but the value is held and

Simulation of Hybrid Dynamic Systems, Fig. 6 Discrete value semantic domains. (a) Transition system. (b) Sampled transition system. (c) Discrete-time transition system. © The MathWorks, Inc.

accessible in between sample times. This is indicated as a continuous evolution domain by the solid horizontal arrow. For digital control systems, the zero-order hold (ZOH) approach is often preferred, whereas for digital image processing systems, a sampled time approach is preferred because it does not affect the signal frequencies.

Finite State Value Behavior

Finite state transition systems behave similar to the integer execution of general computations in Fig. 5. The corresponding semantic domains are shown in Fig. 6 where the finite state notion is depicted as a discrete value domain by the dashed vertical coordinate axis. Note that even though in a computational implementation the states of finite state transition systems are typically identified by integers, semantically the discrete values that represent states are not ordered and are without a metric.

Figure 6a illustrates the semantic domain of transition systems (e.g., automata Alur and Dill (1994) and Petri nets Murata (1989)) based on a discrete progression of discrete state changes. The states as well as the events that effect state changes can be indexed by integer values. In contrast to program code, the events are dynamically generated and not preassigned as the completion of a previous operation. For example, in a Petri net, the tokens in input places of a transition determine whether the transition is enabled. Thus, a scheduler dynamically schedules the transition to be active as the token distribution evolves. This dynamic execution behavior

is depicted in Fig. 6 by the upward pointing arrows.

The semantic domains of the sampled and discrete-time versions of transition systems are illustrated in Figs. 6b, c, respectively. Associating time with the evolution domain enables sample times on a continuous domain, while the execution behavior is discrete and periodic. Given the dynamic scheduling nature, real-time behavior is not a determining factor whether a scheduler is necessary. In its execution, the sampled transition system corresponds to Mealy-type behavior where actions are associated with transitions. The discrete-time transition system corresponds to Moore-type behavior where actions are associated with states.

Continuous Execution Behavior

Executing events on a continuous schedule that is not periodic is the hallmark of discrete-event systems such as the discrete-event system specification (DEVS) (Zeigler et al. 2000). Figure 7a illustrates the semantic domain as a continuous evolution domain and a continuous value domain. Moreover, the discrete events at which value changes occur can be scheduled on a continuous execution domain. Note that transition systems with events occurring on a continuous domain would lead to a discrete value domain and bridge the semantic domains in Figs. 6b and 7a. However, in such transition systems, time itself is part of the state as clocks that can be reset, which creates a continuous value domain.

Behavior that is continuous in all its facets is illustrated in Fig. 7b. This behavior can be specified by switched differential equations, and

Simulation of Hybrid Dynamic Systems, Fig. 7 Continuous evolution and value semantic domains. (a) Discrete-event system. (b) Continuous behavior. (c) Discontinuities. © The MathWorks, Inc.

Simulation of Hybrid Dynamic Systems, Fig. 8 Multidimensional evolution domain. (a) Multiple events. (b) Event sequence. © The MathWorks, Inc.

the evolution domain in hybrid dynamic systems typically is time. Generating the behavior from the differential equations is based on gradients with respect to time. From an existing point in time, the gradients are used to extrapolate the behavior trace to a new point in time that approximates the underlying solution of the differential equation within a certain tolerance. If the behavior changes quickly against time, the behavior gradient is steep, and a small time step may be necessary to meet the tolerance constraint. For slow behavior, a larger time step may be possible. The varying step size along the (horizontal) time axis is depicted in Fig. 7b by horizontal arrows.

Piecewise continuous behavior interspersed with discontinuities is shown in Fig. 7c. The corresponding semantic domain is the same as the continuous behavior in Fig. 7b with the same execution domain and scheduler.

The piecewise continuous behavior with or without discontinuities may be considered to be of a hybrid dynamics nature. Indeed, the change from one piecewise segment of continuous-time behavior to the next may be invoked by the occurrence of a discrete event at the point in time of the transition.

Multidimensional Evolution Domains

In discrete-event systems such as the one illustrated in Fig. 7a, it is often desirable for two events to occur at the same point in time, either because they were scheduled as such independently or because one causes the other with no time delay.

Figure 8a sketches how multiple events at a given point in time would lead to a two-dimensional evolution domain. The double-headed arrow pointing up indicates two such events. Because both of those events have the same time associated with them, in order to distinguish their moment of occurrence (e.g., to order them), an additional index is necessary. Hence, the moment of each event occurrence is represented by a couple, $\langle t, i \rangle$, that comprises the time, t , and an index, i . The index is an element from an ordered set for which the integers may be chosen (even if the metrics are irrelevant). Figure 8a indicates the additional integer dimension by a dashed axis at the time when multiple events occur. Note that many events may be dynamically scheduled at the same point in time before the next time advance.

Similar to discrete-event systems, in hybrid dynamic systems such as illustrated in Fig. 7c,

multiple events may occur at the same point in time. Likewise, an additional dimension would be required in order to separate the moment of occurrence for the multiple events. Figure 8b illustrates the semantic domain with an additional axis to represent the integer part of the evolution domain at the point in time of the discontinuity where the sequence of events takes place.

Piecewise Continuous Systems

Simulation behavior that is piecewise continuous interspersed with discontinuities (e.g., the semantic domains in Figs. 7c and 8b) introduces complications that require special attention from a hybrid dynamic system perspective. Referring to Fig. 8b, four stages of execution can be recognized:

- Continuous behavior evolution that may require a solver reset in case continuity assumptions about magnitude and higher-order derivatives are violated when a discontinuity occurs.
- Detecting when events are generated, which introduces numerical challenges around threshold crossings.
- Support for multiple mode transitions at the same point in time and handling of initial states that are inadmissible or inconsistent.
- Reinitializing state based on discontinuities that are implicit and require handling instantaneous changes as having either 0 or infinitesimal duration.

Of these, first, the numerical challenges of event detection are considered in more detail. Next, challenges in the interaction between mode transition behavior and state reinitialization are studied after which a hyperdense evolution domain is introduced. Finally, caution is drawn to a number of pathological behaviors.

Event Detection

As a behavior evolves continuously, discontinuities are specified to occur when either time or

behavior values exceed certain thresholds. The former are referred to as *time events*, and their time of occurrence is known when they are scheduled. The latter are referred to as *state events* because the behavior values derive from the continuous state and the time of occurrence must be dynamically determined (i.e., as the behavior evolves) (Cellier 1979).

The threshold behavior of state events is specified by inequalities. For example, the thermostat model in Fig. 1 generates events when the temperature falls below *min* as specified by $x \leq \text{min}$ or when the temperature exceeds *max* as specified by $x \geq \text{max}$. Note that the inequalities include the threshold value (they include the equal sign) so as to have clearly defined left limit values to follow the progression of time. These causal (in a temporal sense) limits imply that the intervals of continuous evolution will be left closed and right open (Mosterman et al. 1998a).

Detecting whether the value of a variable crosses a threshold can be reformulated to detect whether a function of that variable crosses 0. This function is called an indicator function, g_α , that takes as input the continuous state of the system, x , the forcing function, u , and time, t . The indicator function may differ per discrete mode, α . The indicator function is used to determine whether a zero crossing, zc , occurred based on its sign:

$$zc_\alpha(x, u, t) = \begin{cases} 1 & \text{if } g_\alpha(x, u, t) > 0 \\ 0 & \text{if } g_\alpha(x, u, t) = 0 \\ -1 & \text{if } g_\alpha(x, u, t) < 0 \end{cases} \quad (2)$$

In case zc changes its sign, an event is generated. For example, for the freewheeling diode model in Fig. 4b when the diode is in its *off* state ($I_D = 0$), an indicator function is

$$g_{off}(V_B, p) = V_B - R \frac{p}{L} \quad (3)$$

where p is the continuous state and V_B is the forcing function, while R and L are parameter values for the resistor and inductor, respectively. When this function changes its sign, a zero-crossing event is generated.

Detecting whether a change of sign occurs typically requires the indicator function to be evaluated positively and negatively. Thus, the indicator function fails to guard against invalid operations (e.g., taking the square root of a negative variable). Rather than returning an error, the invalid operation may return a substitute value that enables successful zero-crossing detection (e.g., the square root may return a negative value based on the absolute value), while the substitute value is never considered an actual (accepted) simulation value. Note that there are techniques to prevent invalid operations but at the cost of efficiency (Esposito et al. 2001).

Even though including the equal sign in threshold comparison results in sound mathematical limit behavior, numerically it is less meaningful. It is well-known in computer programming not to check for equality involving a floating point value, for example, as a loop termination condition. Likewise, detecting whether an indicator function equals 0 is challenging. In a common approach, the 0 level is defined as a “numerical 0” by a tolerance, tol .

$$zc_{\alpha}(x, u, t) = \begin{cases} 1 & \text{if } g_{\alpha}(x, u, t) > tol \\ 0 & \text{if } -tol \leq g_{\alpha}(x, u, t) \leq tol \\ -1 & \text{if } g_{\alpha}(x, u, t) < -tol \end{cases} \quad (4)$$

Though a numerical zero enables the determination that the value of a behavior is (numerically) 0, it complicates detecting an actual crossing of 0 (i.e., a change in sign of the indicator function). The tolerance around 0 allows a behavior to be numerically 0 for a duration of time even if the gradient is nonzero. And so the indicator function may show a sequence of signs at simulation steps as $- \rightarrow 0 \rightarrow 0 \rightarrow +$. It becomes difficult to determine whether this constitutes an actual 0 crossing or whether the behavior first settled at 0 and then started to deviate.

Another key challenge in zero-crossing detection is when an even number of crossings occur within one simulation step. Figure 9 illustrates the situation where the solid circles indicate values of the indicator function computed at two consecutive simulation steps. The dynamics of the indicator function allow its value to change

Simulation of Hybrid Dynamic Systems,

Fig. 9 Zero crossing with even zeros. © The MathWorks, Inc.

from negative to positive and back without a change in sign being detected at the simulation steps. One approach to mitigating this problem is to include the indicator functions as part of the step-size control that the numerical solver uses for generating continuous-time behavior, which introduces additional computational cost.

After detecting a zero crossing, the point in time at which the indicator function changes sign is located within a given tolerance (different from the tolerance on the value domain). Well-understood root-finding methods such as Newton's method or a bisectional search can be used for this purpose (Park and Barton 1996; Zhang et al. 2008).

Mode Transition and State Reinitialization

The inequalities that give rise to mode transition events define where on the semantic domain behavior evolution is admitted and where not. Figure 10 depicts a sequence of mode transitions from left to right. In the initial mode, α_1 , behavior evolves in continuous time from an initial state (the solid circle) according to the vector field lines.

The gray area indicates an area of the semantic domain that is inadmissible. Once the behavior value exceeds the lower bound of the area, a zero-crossing event causes a transition to mode α_2 . The state of the behavior immediately prior to the mode transition taking place is used to initialize behavior in mode α_2 . As shown in Fig. 10, this state is in the inadmissible area of mode α_2 causing an immediate further transition to mode α_3 . Mode α_3 consists of a *jump space* as indicated by the double-headed arrows. In this space, a discontinuous change in the jump direction onto the continuous space takes place. The one-dimensional continuous space is shown as a solid curve with single-headed arrow. An example of this behavior is the freewheeling

Simulation of Hybrid Dynamic Systems, Fig. 10 A sequence of mode changes. © The MathWorks, Inc.

Simulation of Hybrid Dynamic Systems, Fig. 11 Alternative scenario across a sequence of mode changes. © The MathWorks, Inc.

diode circuit in Fig. 4a where the flux of the inductor jumps to 0 when the switch is opened and the diode is still off. Figure 10 shows that in mode α_3 after the discontinuous jump, the state is in the inadmissible space, and a transition to mode α_4 takes place. In mode α_4 , behavior evolves according to the vector field lines with the initial state being the state that resulted from the discontinuous jump in mode α_3 . The behavior evolution in α_4 then reaches an inadmissible area based on time exceeding a threshold value, and further mode transitions may happen.

Figure 11 illustrates an alternative scenario for the sequence of mode changes in Fig. 10. In Fig. 11, the inadmissible space of α_3 is larger such that the initial state after transition from mode α_2 is in the admissible space already. Now, before the discontinuous jump in α_3 takes place, the transition to mode α_4 occurs, and behavior evolution in mode α_4 starts from a different initial value.

Note that the discontinuous change of the behavior state upon entering mode α_3 is part of the behavior specified for that mode instead of a separately specified reinitialization. This is well suited for models where the dynamics are modeled by a system of differential and algebraic equations (DAE). The algebraic part of these

equations defines the jump space, whereas the differential equation part defines the continuous-time behavior evolution space. The continuous behavior evolves on a manifold in the generalized state space, while the jump space corresponds to a projection onto this manifold (Mosterman 2002; van der Schaft and Schumacher 1996; Vergheze et al. 1981).

Alternatively, discontinuous change in the behavior state may be specified when a transition takes place from one mode to the next. For example, the bouncing ball model in Fig. 3 specifies a discontinuous change in velocity when a transition from one mode to the next (albeit the same) mode takes place. From a physics perspective, it may be preferred to have a mode associated with a discontinuity so the configurations of phenomena that cause the discontinuity are clear and to support compositionality. For the bouncing ball model, there is no model of the floor as a source of 0 velocity, while in general in collision models, this is preferred. Figure 12 shows Newton's cradle where in case of a perfectly elastic collision (a coefficient of restitution of 1 for the difference in velocities after and before the collision: $\Delta v^+ = -\Delta v$) with equal masses $m_1 = m_2 = m_3$, the momentum of m_1 first fully transfers to m_2 and

Simulation of Hybrid Dynamic Systems, Fig. 12 A series of reinitializations based on redistribution of momentum. © The MathWorks, Inc.

immediately following to m_3 . By modeling the masses and the collision phenomenon between the colliding masses (m_1 collides with m_2 and m_2 collides with m_3), additional masses are easily added (though great care must be taken when masses are not equal or coefficients of restitution are not 1 Mosterman (2007b)). Note that this model results in a sequence of projections, each of which requires a change in physical state before a new mode of continuous behavior is reached.

A Mode Transition and Reinitialization

Example

Figure 10 illustrates three classes of mode behavior:

- Continuous evolution with a state event in mode α_1 and a time event in mode α_4
- Immediate consecutive transition in mode α_2
- Transition after an instantaneous projection in mode α_3

The electric circuit in Fig. 13 is an example with physical behavior that can be modeled according to each of these. The four inductors ($L1$ through $L4$) store an initial flux ($p1$ through $p4$) that corresponds to each of their currents ($I1$ through $I4$) by the equation $I = \frac{p}{L}$. The resistor, $R1$, follows Ohm's law and creates a voltage difference (positive from the left to right connection), V , based on the current through $R1$, I , as $V = I \cdot R1$. The three diodes ($D1$ through $D3$) either limit a positive voltage difference to 0 (the *on* state) or a negative current to 0 (the *off* state). Similarly, the switch, Sw , enforces a 0 voltage difference when in its *closed* state or a 0 current when in its *open* state. Initially, the switch is in its open state.

Simulation of Hybrid Dynamic Systems, Fig. 13 Electric circuit with different types of discontinuities. © The MathWorks, Inc.

Assume the inductances $L1$, $L2$, $L3$, and $L4$ to be equal to 1.

Consider the scenario that starts with a time event at t_{switch} when the switch is opened while the flux distribution is $p1 = 37$, $p2 = 38.8$, $p3 = 30$, and $p4 = 30$, as shown in Fig. 14a. With the switch closed, the voltages at each of the junctions are 0. The difference in current through $L1$ and $L2$ results in a voltage across $R1$ that is balanced by a corresponding but negative voltage across $L2$. The open switch results in an inconsistent physical state (flux distribution) as opening the branch forces $p2$, $p3$, and $p4$ to be equal (given that $L2 = L3 = L4$). The increase in $p4$ induces a voltage spike as indicated by the + sign in Fig. 14b which causes diode $D3$ to come on and force the junction to a 0 voltage instead as illustrated in Fig. 14c. Because $D3$ comes on as a result of the projected change in flux distribution in Fig. 14b, that flux distribution is never achieved, and redistribution in Fig. 14c is determined based on the original flux distribution in Fig. 14a. Since the intermediate mode in Fig. 14b does not affect the ultimate physical state, it is called a *mythical mode* (Mosterman et al. 1998b; Nishida and Doshita 1987).

Once a consistent flux distribution is determined, it can be adopted as the current state. Because physical in nature, redistributing fluxes is modeled to require an infinitesimal period of time, ϵ , and the event iteration resumes at this new point in time, $t_{\text{switch}} + \epsilon$. Figure 15a shows the adopted consistent state and the voltages and currents that correspond to the new state. Because $p1$ has become larger than $p2$, a negative current would flow through $D1$ and so the diode turns off. Also, the positive current flow through $R1$ that

Simulation of Hybrid Dynamic Systems, Fig. 14 When the switch opens, a new consistent flux distribution is determined. (a) $\langle t_{\text{switch}}, 0 \rangle$. (b) $\langle t_{\text{switch}}, 1 \rangle$. (c) $\langle t_{\text{switch}}, 2 \rangle$. © The MathWorks, Inc.

Simulation of Hybrid Dynamic Systems, Fig. 15 Time is advanced by ϵ to model the physical state (flux) change and a consecutive change follows. (a) $\langle t_{\text{switch}} + \epsilon, 0 \rangle$. (b) $\langle t_{\text{switch}} + \epsilon, 1 \rangle$. © The MathWorks, Inc.

Simulation of Hybrid Dynamic Systems, Fig. 16 Time is advanced by another ϵ to model the physical state (flux) change to introduce a “stutter”. (a) $\langle t_{\text{switch}} + 2\epsilon, 0 \rangle$. (b) $\langle t_{\text{switch}} + 2\epsilon, 1 \rangle$. © The MathWorks, Inc.

is induced by p_2 causes a positive voltage drop. Because the junction to the left of R_1 is at 0 volt, the right-hand port of R_1 is negative. With $L_2 = L_3$ and D_2 off, the voltage drop across both L_2 and L_3 must be equal, which is half the positive voltage drop across R_1 . This negative voltage causes D_2 to come on. Figure 15b shows the new mode with the newly required flux distribution because L_1 and L_2 are now coupled, while L_3 has become decoupled.

Since no further mode changes occur, time is advanced by an infinitesimal amount, and the flux redistribution is adopted as the next physical state. Figure 16a shows this mode and flux distribution as the starting point for the next event iteration. Because the changed flux of L_2

exceeds that of L_3 , D_2 would have a negative current and so D_2 turns off. As a result, L_3 is coupled with L_1 and L_2 , and Fig. 16b shows the corresponding flux redistribution. At this point, no further mode changes occur, time is advanced by an infinitesimal amount, and the redistributed fluxes are adopted.

Figure 17a shows the flux distribution at $t_{\text{switch}} + 3\epsilon$ as well as qualitative values for the voltages and currents. The current through R_1 causes a positive voltage drop that is equally distributed as negative voltage across each of the inductors L_1 , L_2 , and L_3 such that the sum of voltages equals 0. This causes D_2 to turn on, as shown in Fig. 17b. At this point, no further mode changes occur and no flux redistribution

Simulation of Hybrid Dynamic Systems, Fig. 17 A consistent physical state leads to another mode transition with the same consistent physical state. (a) $(t_{\text{switch}} + 3\epsilon, 0)$. (b) $(t_{\text{switch}} + 3\epsilon, 1)$. © The MathWorks, Inc.

is required. Therefore, the sequence of mode changes, and reinitialization terminates so that continuous-time behavior evolution resumes.

Modeling Diode Behavior

Figure 18 shows the diode model used for simulation of the electrical circuit in Fig. 13. Note that the switching conditions do not include 0 (i.e., the voltage must exceed 0 or the current must fall below 0 before being limited to 0). Otherwise, consider the case where a diode is in its *on* state and enforcing a 0 voltage when it is determined that the current would fall below 0. In this situation, the diode would change its state to *off*, but without any changes in the physical state of the circuit, the corresponding voltage would still be 0. Hence, if the switching conditions would include 0, the diode would immediately switch back to its *off* state, and an infinite loop of state changes from *on* to *off* and back arises.

Mathematically, not including the boundary of a switching area may be complicating since the point in time of switching and the limit value at this point are not well defined. A threshold value that must be exceeded eliminates this concern (e.g., switching conditions $I_D \leq I_{th}$ instead of $I_D \leq 0$ and $V_D \geq V_{th}$ instead of $V_D \geq 0$ in Fig. 4b). In simulation, however, the threshold values are a numerical effect when the switching conditions $I_D < 0$ and $V_D > 0$ are used and a threshold value is not strictly necessary.

Also note that the diode model in Fig. 18 is formulated as a finite state machine, whereas sequential logic is not necessary to capture the desired behavior. For example, in a complementarity formulation (van der Schaft and Schumacher 1996), an ideal diode is modeled

Simulation of Hybrid Dynamic Systems, Fig. 18 Finite state machine model of a diode. © The MathWorks, Inc.

by an equality that requires either I_D or V_D to be 0 while complementing the equation with inequalities that require either the voltage to be less than or equal to 0 or the current to be larger than or equal to 0:

$$\begin{aligned} 0 &= V_D I_D \\ -V_D &\geq 0 \\ I_D &\geq 0 \end{aligned} \quad (5)$$

Complementarity formulations are effective in modeling discontinuous behavior of different forms (e.g., rigid body mechanics (Pfeiffer and Glocker 1996)). The use of sequential logic covers a broader range of phenomena in hybrid dynamic systems, though, and sometimes is required (e.g., a latched bitank system (Mosterman and Biswas 1995)).

A Hyperdense Semantic Domain and Numerical Simulation

As the example in Fig. 13 shows, the semantic domain of piecewise continuous models of physical systems requires three aspects:

- A continuous domain for continuous-time behavior evolution

- An infinitesimal domain for discontinuous changes in physical state
- An ordered domain for mode changes

The ability to separate discontinuous change in physical state from mode changes is illustrated in Fig. 14c. With the flux distribution at t_{switch} , the current through $D1$ keeps $D1$ on. The current at $t_{\text{switch}} + \epsilon$, however, is such that $D1$ turns off. If the infinitesimal time step would not be required to advance the flux distribution, $D1$ would turn off before $D2$ turns on, and a different behavior from what is shown in Fig. 15b would be generated.

The set of hyperreals, ${}^*\mathbb{R}$, of nonstandard analysis (Keisler 2012) embeds infinitesimals in the set of reals, $\mathbb{R}$, and so ${}^*\mathbb{R}$ supports the semantic domain for continuous-time behavior evolution and infinitesimal time steps. In addition, the set of integers support the ordered domain of mode changes. Hence, ${}^*\mathbb{R} \times \mathbb{N}$ provides a *hyperdense* semantic domain that supports the necessary detail to separately evaluate the discontinuous and mode change behavior (Mosterman et al. 2014).

Numerical simulation requires discrete-time steps to evolve behavior on the reals, $\mathbb{R}$, while the infinitesimal time advances can be captured by an integer count of infinitesimal steps during mode transition sequences. The resulting domain for numerical simulation becomes three dimensional as $\mathbb{R} \times \mathbb{N} \times \mathbb{N}$. For example, the mathematical moment of evaluation in Fig. 14a is $\langle t_{\text{switch}}, 0 \rangle$ with the numerical simulation step being identified as $\langle t_{\text{switch}}, 0, 0 \rangle$. Likewise, the mathematical moment of evaluation in Fig. 17b is $\langle t_{\text{switch}} + 3\epsilon, 1 \rangle$ with the numerical simulation step being identified as $\langle t_{\text{switch}}, 3, 1 \rangle$.

The results of a simulation with HYBR-SIM (Mosterman 2002) where $R1 = L1 = L2 = L3 = L4 = 1$ from time 0 to 0.5s are shown in Fig. 19. Before the switch is opened at $t = t_{\text{switch}} = 0.2s$, the flux $p2$ decreases because of the dissipative effect of $R1$. After the switch is opened and the mode transition sequence has converged, the fluxes $p1$ and $p2$ decrease equally (overlapping traces in the graph) because $D1$ is *off*. Figure 20 shows the mode transition

sequence at $t = 0.2s$ in detail where the indices represent the evolution tuples as 1 : $\langle 0.2, 0, 0 \rangle$, 2 : $\langle 0.2, \epsilon, 0 \rangle$, 3 : $\langle 0.2, 2\epsilon, 0 \rangle$, 4 : $\langle 0.2, 3\epsilon, 0 \rangle$, and finally 5 : $\langle 0.2, 3\epsilon, 1 \rangle$. Figure 20a shows the consistent modes for each point in time including the initial mode when the switch is still closed. The overall mode is comprised of a combination of the discrete state of three junctions where the first and last junction are fully determined by the state of the corresponding diodes, $D1$ and $D3$, respectively. The state of the second junction depends on the combination of the switch, Sw , and diode, $D2$. If the switch is closed or the diode is *on*, the junction is *on*, whereas the junction is *off* otherwise. Figure 20b shows the consistent flux distributions for each of the modes in Fig. 20a with the initial distribution of the fluxes immediately before the switch is opened (t_{switch}). Note that the intermediate modes (before an accepted flux distribution is reached) are not logged in simulation; only values in time as simulated hyperreals (i.e., a tuple of time and number of infinitesimal steps from a point in real time) are shown.

Pathological Behavior

Simulation of mode transition behavior may encounter a number of behaviors that are challenging to handle. First, the hybrid dynamic system may exhibit sliding behavior as illustrated in Fig. 21. When the behavior reaches the switching (inadmissible) area (where the boundary is included in the switching condition) in mode α_1 , a transition is made to mode α_2 . The behavior in mode α_2 starts on the boundary of the switching (inadmissible) area where the boundary is not included. As soon as continuous-time simulation restarts, the mode transition back to α_1 occurs. After a similarly small time step, the dynamic field lines push the behavior in mode α_1 back to the switching boundary, and repeated switching occurs with the minimum step size that the numerical simulation allows. Such behavior is, for example, the purview of *sliding mode control* (such as used in antilock braking systems), and special simulation algorithms (Mosterman et al. 1999) can be used to filter out the fast

Simulation of Hybrid Dynamic Systems,

Fig. 21 Sliding mode behavior. © The MathWorks, Inc.

switching behavior while retaining the slow dynamic behavior along the switching boundary. Second, in case of overlapping switching areas in Fig. 21, as soon as the switching boundary in mode α_1 is reached, the behavior enters an infinite loop of mode transitions that occur in 0 time. Hence, simulation of the dynamic behavior halts, which is typically undesirable (e.g., because this is inconsistent with observed behavior in the

physical world). This behavior may be difficult to determine as present in a hybrid dynamic system model and often cannot be detected other than when exhibited during simulation. Third, mode transitions may occur at progressively smaller time steps such as described for the bouncing ball model in Fig. 3. In an ideal mathematical model, time converges to a limit point. In a numerical simulation, behavior may be

ill defined when the numerical time step moves past the limit point. Note that the existence of a limit point may be difficult to detect, even during simulation.

Multiparadigm Modeling

Modern engineered systems increasingly rely on computational elements (e.g., microprocessors, microcontrollers, and field-programmable gate arrays) and a communication infrastructure (e.g., wired or wireless networks). Even if such engineered systems are not intrinsically hybrid dynamic systems, the physics are often best represented at a macroscopic level by models with continuous-time semantics, and the computation is often best represented by models with discrete-time or discrete-event semantics. A structure of such systems with the various different components is shown in Fig. 22. At the bottom is the physical world. Sensors and actuators connect the physical world with the digital world via built-in computational elements. The network connectivity of these sensors and actuators enables communication with other sensors and actuators as well as

powerful microprocessors or other computational elements.

Different formalisms are typically required to model the behavior of the various different components. At the microprocessor level, program code (semantic domain of Fig. 5a), synchronous data flow and difference equations (semantic domain of Fig. 5b), as well as state transition diagrams (semantic domain of Fig. 6b) are often used. Modeling network behavior generally requires the ability to capture different event densities over time for which discrete-event systems are preferred (semantic domain of Fig. 7a) (Cassandras et al. 2006; Cervin et al. 2003; Zeigler et al. 2000). Because of the interaction with the continuous-time models of the physical world, sensors and actuators are often modeled as discrete time with zero-order hold (semantic domain of Fig. 5c). Finally, the macroscopic behavior of physical systems is well represented by differential equations with discontinuous changes that occur at specific points in time (semantic domain of Fig. 7c).

The combination of this scala of modeling formalisms with the variety of semantic domains to be used for simulation is the purview of multiparadigm modeling (Mosterman and Vangheluwe

Simulation of Hybrid Dynamic Systems,
Fig. 22 Multiple semantic domains in engineered system modeling. © The MathWorks, Inc.

2004). Hybrid dynamic systems are thus fundamental to multiparadigm modeling where hybrid means combining different semantic domains.

Behavior Generation Engines

In terms of efficient execution, handling continuous time is the first and foremost challenge. Continuous-time behavior progresses along the gradient of differential equations. When thresholds are exceeded, zero-crossing events are detected and then located, and their effect is evaluated before time progresses further. Because of the progression of state values along time, this is called time-driven execution. In contrast, discrete-event behavior schedules events in the future by keeping an event calendar. The event that is scheduled earliest in time is removed from the calendar, current time is set to the event time, and the event is processed. This processing may cause further events to be scheduled or already scheduled events to be canceled (removed from the calendar). Once processing completes, the current time is set to the time of the earliest scheduled event, and the event is processed. Because time evolves in discrete steps based on scheduled events, this is called an event-driven execution (Mosterman 2007a).

Figure 23 depicts a time-driven execution engine on the left-hand side and an event-driven execution engine on the right-hand side. The bottom traces represent continuous-time evolution on the left and discrete-event evolution on the right. Note that at event times (e.g., zero-crossing events or scheduled discrete events), multiple evaluation steps may take place that may be scheduled as events in turn. Also, in case of piecewise continuous behavior, a series of infinitesimal steps may be scheduled before time-driven execution resumes.

Statically scheduled events because of periodic behavior (e.g., discrete time with a single or multiple rates and synchronous data flow) can either be included in a time-driven or an event-driven execution engine. Figure 23 shows discrete-time behavior as part of the time-driven execution engine because the zero-order hold

behavior closely aligns with the continuous-time behavior and is typically used because of interacting behavior. Without hold behavior, complicated semantic challenges may arise in interacting with minor time steps of numerical solvers (Denckla and Mosterman 2008). Otherwise, the discrete-time behavior schedules a time event, and the numerical solver will evaluate the differential equations at that point in time, then evaluate the discrete-time operations, and resume continuous-time behavior.

Figure 23 shows synchronous behavior as part of the event-driven execution engine because of the discretized time domain. Also, data flow comes in statically scheduled and dynamically scheduled forms and hence is more closely related to discrete-event systems.

While the architecture in Fig. 23 allows the most efficient simulation mechanism (time driven vs. event driven) for each evolution domain, the moments of interaction must be handled efficiently as well. In one form, the interaction may consist of the time-driven model part scheduling or canceling an event for the event-driven model part (e.g., when the strength of a communicating signal falls below a threshold level, a message may be sent to a transmitter). In another form, the event-driven model part may schedule an event for the time-driven model part (e.g., a network message may set a threshold value for a valve to open). As a result, when an interacting event is scheduled or canceled, the behavior evolution of the receiving model part may change.

Two basic approaches can be employed to handle the interaction effects:

- With *conservative execution*, the engines operate in lock step. The event-driven execution engine may change its current time to be ahead of the current time of the time-driven execution engine but first stores the full state of the event-driven execution engine. The time-driven execution engine then catches up before the event-driven engine makes another step and the process repeats. If the time-driven model part generates an interacting event while in the process of catching up, the event-driven execution engine restores its

Simulation of Hybrid Dynamic Systems,

Fig. 23 Time-driven and event-driven execution engines. © The MathWorks, Inc.

full state, the interacting event is added to the event calendar, and the interacting event is processed next.

- With *optimistic execution*, the engines are allowed to process more than one step ahead of each other. For example, it may be efficient both for the event-driven engine and the time-driven engine if one processes a number of events before the other catches up. In this scheme, it becomes key to determine when the full engine state should be stored to enable quick reconstruction of the state at which an interacting event occurred. In advanced methods, an intermediate state may be reconstructed in approximation by an interpolation polynomial (which may be more efficient than reconstructing a state via simulation).
- The cross product of evolution domains such as a continuous domain combined with an integer domain.
- A combination of different semantic domains such as discrete-time and continuous-time behavior.
- A combination of different execution engines, for example, an event-driven engine combined with a time-driven engine.

Generating an event from a continuous-time behavior via zero-crossing detection and location is both challenging to be sound and to be efficient. Generating a new mode of continuous-time behavior with a consistent continuous-time state from discrete changes is challenging as well. In particular, among the richest of hybrid dynamic system behaviors is the piecewise continuous semantic domain. With a continuous value domain, a three-dimensional hyperdense evolution domain emerges to account for sequences of state reinitialization and mode transition behavior.

Note that modeling mode transitions as either occurring in 0 time or in infinitesimal time has been shown to be an important consideration beyond simulation, namely, in reasoning about discontinuous change, with corresponding direct and approximate reasoning methods, respectively (Nishida and Doshita 1987).

Conclusions

Hybrid dynamic systems may refer to various combinations of behavior and execution semantics:

- A continuous evolution domain with a combination of continuous and discrete behavior in the value domain.

Much progress has been made in hybrid dynamic system simulation. Still, open challenges remain. These include how to:

- Solve or resolve some of the pathological behaviors.
 - Statically (i.e., before simulation) determine whether the simulation may reach an infinite loop of 0 time mode transitions.
 - Find the limit points for converging time if present.
 - Develop robust simulation algorithms for higher-dimensional sliding behavior.
- Simulate impulsive behavior (e.g., support comparison of impulsive quantities such as voltage spikes and impulsive forces).

As a caution in closing, combining continuous behavior with discrete changes results in behavior that is highly sensitive to perturbations in the initial state and parameters of the model but also to the solver parameters. Without a fundamental solution, good practice is to check sensitivity effects by using different solvers and parameters.

Single-Photon Coherent Feedback Control and Filtering

Guofeng Zhang

Department of Applied Mathematics, The Hong Kong Polytechnic University, Hong Kong, China

Abstract

A light field is in a k -photon state if it contains *exactly* k photons. Due to their highly quantum nature, photon states hold promising applications in quantum communication, computing, metrology, and simulations. Recently, there has been rapidly growing interest in the generation and manipulation of various photon states. A new and important problem in the field of control engineering is: How to analyze

and synthesize quantum systems driven by photon states to achieve pre-specified control performance? In this survey, we introduce single-photon states and show how a quantum linear system processes a single-photon input and how to use linear coherent feedback networks to shape the temporal pulse of a single photon. A single-photon filter is also presented. (An extended version of this survey can be found at [arXiv:1902.10961](https://arxiv.org/abs/1902.10961).)

Keywords

Quantum control systems · Filtering · Coherent feedback control

Notation $|0\rangle$ denotes the vacuum field state. Given a column vector of operators or complex numbers $X = [x_1, \dots, x_n]^\top$, the adjoint operator or complex conjugate of X is denoted by $X^\# = [x_1^*, \dots, x_n^*]^\top$. Let $X^\dagger = (X^\#)^\top$ and $\check{X} = [X^\top \ X^\dagger]^\top$. The commutator between operators A and B is defined to be $[A, B] = AB - BA$. Given two constant matrices $U, V \in \mathbb{C}^{r \times k}$, a doubled-up matrix $\Delta(U, V)$ is defined as $\Delta(U, V) = [U \ V; V^\# \ U^\#]$. Finally, $\delta(t - r)$ is the Dirac delta function, and $\xi[i\omega]$ is the complex domain function obtained after Fourier transforming a time-domain function $\xi(t)$.

Single-Photon States

Let $b(t)$ denote the annihilation operator of a light field. Then a continuous-mode single-photon state $|1_\xi\rangle$ of the field can be defined as $|1_\xi\rangle \equiv \mathbf{B}^*(\xi) \triangleq \int_{-\infty}^{\infty} b^*(t)\xi(t)dt |0\rangle$, where $\xi(t)$ is an L^2 integrable function satisfying $\int_{-\infty}^{\infty} |\xi(t)|^2 dt = 1$ and $b^*(t)$ (the adjoint of $b(t)$) is the creation operator of the field. Under the state $|1_\xi\rangle$, the quantum stochastic process $b(t)$ has zero mean, and the covariance function, defined by $R(t, r) \triangleq \langle 1_\xi | \check{b}(t)\check{b}^\dagger(r) | 1_\xi \rangle$, satisfies

$$R(t, r) = \delta(t - r) \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} + \begin{bmatrix} \xi(r)^* \xi(t) & 0 \\ 0 & \xi(r) \xi(t)^* \end{bmatrix}.$$

For example, the Gaussian pulse shape of a single-photon state $|1_\xi\rangle$ can be given by

$$\xi(t) = \left(\frac{\Omega^2}{2\pi}\right)^{\frac{1}{4}} \exp\left(-\frac{\Omega^2}{4}(t - \tau)^2\right), \quad (1)$$

where τ is the photon peak arrival time. Applying Fourier transform to $\xi(t)$, we get

$$|\xi[i\omega]|^2 = \frac{1}{\sqrt{2\pi}(\Omega/2)} \exp\left(-\frac{\omega^2}{2(\Omega/2)^2}\right).$$

Hence, Ω is the frequency bandwidth of the single-photon wavepacket.

Linear Response to Single-Photon States

In this section, we discuss how a quantum linear system G processes single-photon states. Let G be an optical cavity having a single internal mode (a quantum harmonic oscillator represented by its annihilation operator a) and interacting with an external light field represented by its annihilation operator b . Because a is an internal mode, it and its adjoint operator a^* satisfy the canonical commutation relation $[a, a^*] = 1$, in contrast to the singular commutation relation $[b(t), b(r)^*] = \delta(t - r)$ for the free propagating field. Let ω_c be the detuned frequency between the resonant frequency of the internal mode a and the central frequency of the external light field b . Let κ be the half linewidth of the cavity. Then the dynamics of this system can be described by $da(t) = -(i\omega_c + \frac{\kappa}{2})a(t)dt - \sqrt{\kappa}dB(t)$ and $dB_{\text{out}}(t) = \sqrt{\kappa}a(t)dt + dB(t)$, where $B(t) = \int_0^t b(\tau)d\tau$ is the integrated field input operator (a quantum Wiener process). More discussions on open quantum systems can be found in, e.g., Gardiner and Zoller (2004), Wiseman and Milburn (2009), and Zhang et al. (2018).

Theorem 1 (Zhang and James 2013, Proposition 2)

Assume there is one input field which is in the single photon state $|1_\xi\rangle$. Then the steady-state output field state for the linear quantum system

Single-Photon Coherent Feedback Control and Filtering, Fig. 1 A linear quantum feedback network composed of an optical cavity and a beam splitter

G is $\rho_{\text{out}} = (\mathbf{B}^*(\xi_{\text{out}}^-) - \mathbf{B}(\xi_{\text{out}}^+))\rho_{\text{field},g}(\mathbf{B}^*(\xi_{\text{out}}^-) - \mathbf{B}(\xi_{\text{out}}^+))^*$, where $\Xi_G[s]$ is the transfer function of the system G , $\Delta(\xi_{\text{out}}^-[s], \xi_{\text{out}}^+[s]) = \Xi_G[s]\Delta(\xi[s], 0)$, and $\rho_{\text{field},g}$ is the density operator for the output field with zero mean and covariance function $R_{\text{out}}[i\omega] = \Xi_G[i\omega]R_{\text{in}}[i\omega]\Xi_G[i\omega]^\dagger$ with $R_{\text{in}}[i\omega] = [1 \ 0; 0 \ 1]$. In particular, for an empty optical cavity, we have $\xi_{\text{out}}^+[s] \equiv 0$ and $R_{\text{out}}[i\omega] \equiv R_{\text{in}}[i\omega]$; in other words, the steady-state output is a single-photon state $|1_{\xi_{\text{out}}^-}\rangle$.

Single-Photon Pulse Shaping

In this section, we show how a coherent feedback network can be constructed to manipulate the temporal pulse shape of a single-photon state.

If an optical cavity is driven by a single-photon state $|1_\xi\rangle$, by Theorem 1, the output pulse shape in the frequency domain is $\eta_1[i\omega] = \frac{i(\omega + \omega_c) - \frac{\kappa}{2}}{i(\omega + \omega_c) + \frac{\kappa}{2}}\xi[i\omega]$. Now we put the cavity in a feedback network closed by a beam splitter, as shown in Fig. 1. Let the beam splitter be defined by a two-by-two matrix $S_{\text{BS}} = [\sqrt{\gamma} \ e^{-i\phi}\sqrt{1-\gamma}; -e^{i\phi}\sqrt{1-\gamma} \ \sqrt{\gamma}]$ with $0 < \gamma < 1$. The whole system from b_0 to b_3 in Fig. 1 is still a quantum linear system that is driven by the single-photon state $|1_\xi\rangle$ for the input b_0 . By Theorem 1, the pulse shape for the output field b_3 is $\eta_3[i\omega] = (-\frac{1-\sqrt{\gamma}}{1+\sqrt{\gamma}}(\omega + \omega_c)i + \frac{\kappa}{2})/(\frac{1-\sqrt{\gamma}}{1+\sqrt{\gamma}}(\omega + \omega_c)i + \frac{\kappa}{2})\xi[i\omega]$. Fix $\tau = 0$ and $\Omega = 2.92$ for the Gaussian single-photon state (1) and $\omega_c = 0$ and $\kappa = 1$ for the optical cavity (Fig. 2). The temporal pulse shapes $\xi(t)$, $\eta_1(t)$ and $\eta_3(t)$ are plotted in Fig. 2.

Single-Photon Coherent Feedback Control and Filtering, Fig. 2 $|\xi(t)|^2$ denotes the detection probability of input photon, $|\eta_1(t)|^2$ denotes the detection probability of output photon in the case of the optical cavity alone,

$|\eta_3(t)|^2$ are the detection probabilities of output photon in the coherent feedback network (Fig. 1) with different beamsplitter parameters γ

Single-Photon Coherent Feedback Control and Filtering, Fig. 3 Single-photon filtering

Single-Photon Filtering

As discussed above, a single-photon light field has statistical properties. Hence, it makes sense to study the filtering problem of a quantum system driven by a single-photon field. Single-photon filters were first derived in Gough et al. (2012), and their multiphoton version was developed in Song et al. (2016). The basic setup is given in Fig. 3. In Fig. 3, G is a quantum system which is driven by a single photon of pulse shape ξ . After interaction, the output field is measured, and the measurement outcome is $Y(t) = B_{\text{out}}(t) + B_{\text{out}}^*(t)$. Y_t enjoys the self-non-demolition property $[Y(t), Y(r)] = 0$ and the non-demolition property $[X(t), Y(r)] = 0$ for all $t_0 \leq r \leq t$, where X is an arbitrary system operator and t_0 is the time when the system and field start interaction. The quantum conditional expectation is defined as $\pi_t(X) \equiv \mathbb{E}[X(t)|\mathcal{Y}_t]$, where $\mathbb{E}$ denotes the expectation and the commutative von

Neumann algebra $\mathcal{Y}_t$ is generated by the past measurement observations $\{Y(s) : t_0 \leq s \leq t\}$. The *conditioned* system density operator $\rho(t)$ can be obtained by means of $\pi_t(X) = \text{Tr}[\rho(t)^\dagger X]$. It turns out that $\rho(t)$ is a solution to a system of stochastic differential equations, which is called the *quantum filter* whose exact form can be found in Gough et al. (2012, Eq. (42)).

Summary and Future Directions

In this section, we discuss three possible future research directions.

In this survey, the single photons are characterized in terms of their temporal pulse shapes, which are L^2 integrable functions. In this sense, these photon states are continuous-variable (CV) states. In addition to CV photonic states, there are discrete-variable (DV) photonic states, for example, number states and polarization states.

In Zhang and James (2013), the linear systems theory, summarized in section “[Linear Response to Single-Photon States](#),” was applied to derive the output of a quantum linear system driven by a coherent state and a single-photon state. If the pulse information is ignored and only the number of photons is counted, the results reduce to those in the physics literature; see, e.g. Bartley et al. (2012). It can be easily shown that the general framework still works if the coherent state is replaced by a squeezed-vacuum state. Nonetheless, it is unclear to what extent that the mathematical methods proposed for photonic CV states also work for DV photonic states.

In the section “[Single-Photon Pulse Shaping](#),” we have discussed the problem of single-photon pulse shaping by using a very simple example (see Fig. 1), where the system G is an optical cavity. Clearly, a passive quantum linear controller K can be added into the network in Fig. 1. Adding a passive quantum linear controller increases flexibility of the pulse shaping of the input single photon. There may be one of the future research directions.

Finally, in measurement-based feedback control of quantum systems, *real-time* implementation of a quantum filter is essential. In the case of a two-level system driven by a vacuum field, a system of three stochastic differential equations (SDEs) is sufficient for filtering. However, for a two-level system driven by a single photon, the single-photon filter consists of a system of 9 SDEs (Gough et al. 2012, Eq. (42)), and a two-photon filter consists of 30 SDEs (Song et al. 2016). Thus, numerically efficient and reliable implementation of single- or multi-photon filters is an important problem in the measurement-based feedback control of quantum systems driven by photons. There is presently very few pieces of work in the direction; a recent attempt using quantum information geometry theory can be found in Gao et al. (2019)

Singular Trajectories in Optimal Control

Bernard Bonnard¹ and Monique Chyba²

¹Institute of Mathematics, University of Burgundy, Dijon, France

²University of Hawaii-Manoa, Manoa, HI, USA

Abstract

Singular trajectories arise in optimal control as singularities of the end-point mapping. Their importance has long been recognized, at first in the Lagrange problem in the calculus of variations where they are lifted into abnormal extremals. Singular trajectories are candidates as minimizers for the time-optimal control

problem, and they are parameterized by the maximum principle via a pseudo-Hamiltonian function. Moreover, besides their importance in optimal control theory, these trajectories play an important role in the classification of systems for the action of the feedback group.

Keywords

Abnormal extremals · End-point mapping · Martinet flat case in sub-Riemannian geometry · Pseudo-hamiltonian

Introduction

The concept of singular trajectories in optimal control corresponds to *abnormal extrema* in optimization. Suppose that a point $x^* \in X \simeq \mathbb{R}^n$ is a point of extremum for a smooth function $\mathcal{L} : \mathbb{R}^n \rightarrow \mathbb{R}$ under the equality constraints $F(x) = 0$ where $F : X \rightarrow Y$ is a smooth mapping into $Y \simeq \mathbb{R}^p$, $p < n$. The *Lagrange multiplier rule* (Agrachev et al. 1997) asserts the existence of nonzero pairs (λ_0, λ^*) of Lagrange multipliers such that $\lambda_0 \mathcal{L}'(x^*) + \lambda^* F'(x^*) = 0$. The *normality condition* is given by $\lambda_0 \neq 0$, and the abnormal case corresponds to the situation when the rank of $F'(x^*)$ is strictly less than p .

Abnormal extremals have played an important role in the standard calculus of variations (Bliss 1946). Indeed, consider a classical Lagrange problem:

$$\frac{dx}{dt}(t) = F(x(t), u(t)), \quad \min_{u(\cdot)} \int_0^T L(x(t), u(t)) dt \\ x(0) = x_0, x(T) = x_1,$$

where $x(t) \in X \simeq \mathbb{R}^n$, $u(t) \in \mathbb{R}^m$, F and L are smooth. Using an infinite dimensional framework, the Lagrange multiplier rule still holds and an abnormal extremum corresponds to a singularity of the set of constraints.

Definition

Consider a system of $\mathbb{R}^n$: $\frac{dx}{dt}(t) = F(x(t), u(t))$ where F is a smooth mapping from $\mathbb{R}^n \times \mathbb{R}^m$

into $\mathbb{R}^n$. Fix $x_0 \in \mathbb{R}^n$ and $T > 0$. The *end-point mapping* is the mapping $E^{x_0, T} : u(\cdot) \in \mathcal{U} \rightarrow x(T, x_0, u)$ where $\mathcal{U} \subset L^\infty[0, T]$ is the set of admissible controls such that the corresponding trajectory $x(\cdot, x_0, u)$ is defined on $[0, T]$. A control $u(\cdot)$ and its corresponding trajectory are called *singular* on $[0, T]$ if $u(\cdot) \in \mathcal{U}$ is such that the Fréchet derivative $E'^{x_0, T}$ of the end-point mapping is not of full rank n at $u(\cdot)$.

Fréchet Derivative and Linearized System

Given a reference trajectory $x(\cdot)$, $t \in [0, T]$, associated to $u(\cdot)$ with $x(0) = x_0$, and solution of $\frac{dx}{dt}(t) = F(x(t), u(t))$, the system

$$\delta \dot{x}(t) = A(t)\delta x(t) + B(t)\delta u(t)$$

with

$$A(t) = \frac{\partial F}{\partial x}(x(t), u(t)), \quad B(t) = \frac{\partial F}{\partial u}(x(t), u(t))$$

is called the *linearized system* along the control-trajectory pair $(u(\cdot), x(\cdot))$.

Let $M(t)$ be the fundamental matrix, $t \in [0, T]$ solution of

$$\dot{M}(t) = A(t)M(t), \quad M(0) = I_n.$$

Integrating the linearized system with $\delta x(0) = 0$, one gets the following proposition.

Proposition 1 *The Fréchet derivative of $E^{x_0, T}$ at $u(\cdot)$ is given by*

$$E_u'^{x_0, T}(v) = M(T) \int_0^T M^{-1}(t)B(t)v(t)dt.$$

Computation of the Singular Trajectories and Pontryagin Maximum Principle

According to the previous computations, a control $u(\cdot)$ with corresponding trajectory $x(\cdot)$ is singular on $[0, T]$ if the Fréchet derivative $E'^{x_0, T}$

is not of full rank at $u(\cdot)$. This is equivalent to the condition that the linearized system is *not controllable* (Lee and Markus 1967).

Such a condition is difficult to verify directly since the linearized system is time-dependent and the computation is associated to the Maximum Principle (Pontryagin et al. 1962).

Let p^* be a nonzero vector such that p^* is orthogonal to $\text{Im}(E^{x_0, T})$ and let $p(t) = p^* M(T) M^{-1}(t)$; then $p(\cdot)$ is solution of the *adjoint system*

$$\dot{p}(t) = -p(t) \frac{\partial F}{\partial u}(x(t), u(t))$$

and satisfies almost everywhere the equality

$$p(t) \frac{\partial F}{\partial u}(x(t), u(t)) = 0.$$

Introduce the *pseudo-Hamiltonian* $H(x, p, u) = \langle p, F(x, u) \rangle$, where $\langle \cdot, \cdot \rangle$ is the Euclidean inner product, one gets the following characterization.

Proposition 2 *If (x, u) is a singular control-trajectory pair on $[0, T]$, then there exists a nonzero adjoint vector $p(\cdot)$ defined on $[0, T]$ such that (x, p, u) is solution a.e. of the following equations:*

$$\begin{aligned} \frac{dx}{dt} &= \frac{\partial H}{\partial p}(x, p, u), \quad \frac{dp}{dt} = -\frac{\partial H}{\partial x}(x, p, u) \\ \frac{\partial H}{\partial u}(x, p, u) &= 0. \end{aligned}$$

Application to the Lagrange Problem

Consider the problem

$$\frac{dx}{dt}(t) = F(x(t), u(t)), \min \int_0^T L(x(t), u(t)) dt$$

with $x(0) = x_0, x(T) = x_1$.

Introduce the *cost-extended pseudo-Hamiltonian*: $\tilde{H}(x, p, u) = \langle p, F(x, u) \rangle + p_0 L(x, u)$; it follows that the maximum principle is equivalent to the Lagrange multiplier rule presented in the introduction:

$$\begin{aligned} \frac{d\tilde{x}}{dt} &= \frac{\partial \tilde{H}}{\partial \tilde{p}}(\tilde{x}, \tilde{p}, u), \quad \frac{d\tilde{p}}{dt} = -\frac{\partial \tilde{H}}{\partial \tilde{x}}(\tilde{x}, \tilde{p}, u) \\ \frac{\partial \tilde{H}}{\partial u}(\tilde{x}, \tilde{p}, u) &= 0 \end{aligned}$$

where $\tilde{x} = (x, x^0)$ is the extended state variable solution of $\frac{dx}{dt} = F(x, u)$, $\frac{dx^0}{dt} = L(x, u)$ and $\tilde{p} = (p, p_0)$ is the extended adjoint vector. One has the condition $\langle \tilde{p}, \tilde{E}_u^{x_0, T}(v) \rangle = 0$ where $\tilde{E}_u^{x_0, T}$ is the cost-extended end-point mapping.

The Role of Singular Extremals in Optimal Control

While the traditional treatment in optimization of singular extremals is to consider them as a pathology, in modern optimal control, they play an important role which is illustrated by two examples from *geometric optimal control*.

Singular Trajectories in Quantum Control

Up to a normalization (Lapert et al. 2010), the time minimization *saturation problem* is to steer in minimum time the magnetization vector $M = (x, y, z)$ from the north pole of the Bloch Ball $N = (0, 0, 1)$ to its center $O = (0, 0, 0)$. The evolution of the system is described by the *Bloch equation* in nuclear magnetic resonance (Levitt 2008)

$$\frac{dx}{dt} = -\Gamma x + u_2 z$$

$$\frac{dy}{dt} = -\Gamma y - u_1 z$$

$$\frac{dz}{dt} = \gamma(1 - z) + u_1 y - u_2 x$$

where (Γ, γ) are proportional to the inverse of the relaxation times and $u = (u_1, u_2)$ is the control radio frequency-magnetic field bounded according to $|u| \leq M$. Due to the z -symmetry of revolution, one can restrict the problem to the 2D single-input case

$$\frac{dy}{dt} = -\Gamma y - uz, \quad \frac{dz}{dt} = \gamma(1 - z) + uy$$

that can be written as $\frac{dq}{dt} = F(q) + uG(q)$.

According to the maximum principle, the time-optimal solutions are the concatenations of *regular extremals* for which $u(t) = M \text{sign}\langle p(t), G(q(t)) \rangle$ and singular arcs where $\langle p(t), G(q(t)) \rangle = 0, \forall t$, and $p(t)$ is solution of the adjoint system. Differentiating with respect of time and using the *Lie bracket* notation $[X, Y](q) = \frac{\partial X}{\partial q}(q)Y(q) - \frac{\partial Y}{\partial q}(q)X(q)$, we get

$$\langle p, [G, F](q) \rangle = 0,$$

$$\langle p, [[G, F], G](q) \rangle + u \langle p, [[G, F], F](q) \rangle = 0.$$

This leads to two singular arcs:

- The vertical line $y = 0$, corresponding to the z -axis of revolution
- The horizontal line $z = \frac{\gamma}{2(\gamma - \Gamma)}$

The interesting physical case is when $2\Gamma > 3\gamma$ where the vertical singular line is such that $-1 < \frac{\gamma}{2(\gamma - \Gamma)} < 0$. In this case, the time minimum solution is represented on Fig. 1. On Fig. 2 we draw the experimental solution in the deoxygenated blood case, compared with the standard inversion recovery sequence.

Singular Trajectories in Optimal Control, Fig. 1 The computed optimal solution is the following concatenation: bang arc σ'_M with the horizontal singular arc σ_{sh} followed by a bang arc P and finally the singular vertical arc σ_{sv}

Abnormal Extremals in SR Geometry

Sub-Riemannian geometry was introduced by R.W. Brockett as a generalization of Riemannian geometry (Brockett 1982; Montgomery 2002) with many applications in control (for instance, in motion planning (Bellaïche et al. 1998; Gauthier and Zakalyukin 2006) and quantum control). Its formulation in the framework of control theory is

$$\dot{q}(t) = \sum_{i=1}^m u_i(t) F_i(q(t)), \quad \min_{u(\cdot)} \int_0^T \left(\sum_{i=1}^m u_i^2(t) \right) dt$$

where $q \in U$ open set in $\mathbb{R}^n$, $m < n$ and $F_1, \dots, F_m$ are smooth vector fields which forms an orthonormal basis of the distribution they generate.

According to the maximum principle, normal extremals are solutions of the Hamiltonian vector field $\mathbf{H}_n$, $H_n = \frac{1}{2}(\sum_{i=1}^m H_i(q, p)^2)$, $H_i = \langle p, F_i(q) \rangle$ for $i = 1, \dots, m$. Again abnormal extremals can be computed by differentiating the constraint $H_i = 0$ along the extremals. Their first occurrence takes place in the so-called Martinet flat case: $n = 3, m = 2$, F_1, F_2 are given by

$$F_1 = \frac{\partial}{\partial x} + \frac{y^2}{2} \frac{\partial}{\partial z}, \quad F_2 = \frac{\partial}{\partial y}$$

where $q = (x, y, z) \in U$ neighborhood of the origin, and the metric is given by $ds^2 = dx^2 + dy^2$. The singular trajectories are contained in the Martinet plane $M : y = 0$ and are the lines $z = z_0$. An easy computation shows that they are optimal for the problem. We represent below the role of the singular trajectories when computing the sphere of small radius, from the origin, intersected with the Martinet plane (Fig. 3).

Summary and Future Directions

Singular trajectories play an important role in many optimal control problem such as in

Singular Trajectories in Optimal Control,

Fig. 2 Experimental result. Usual inversion sequence in *green*, optimal computed sequence in *blue*

quantum control and cancer therapy (Schättler and Ledzewicz 2012). They have to be carefully analyzed in any applications; in particular in Boscain and Piccoli (2006) the authors provide for single-input systems in two dimensions a classification of optimal synthesis with singular arcs.

Additionally, from a theoretical point of view, singular trajectories can be used to compute feedback invariants for nonlinear systems (Bonnard and Chyba 2003). In relation, a purely mathematical problem is the classification of distributions describing the nonholonomic constraints in sub-Riemannian geometry (Montgomery 2002).

Sliding Mode Control: Finite-Time Observation and Regulation

Arie Levant

Department of Applied Mathematics, Tel-Aviv University, Ramat-Aviv, Israel

Abstract

Sliding Modes (SMs) are used to control uncertain systems by properly choosing and exactly keeping constraints involving system outputs and their derivatives. The constraint relative degree turns out to be the main approach parameter. Modern SM control (SMC) applies real-time precise differentiators and establishes the constraint exactly and in finite time. SMC systems are robust to noisy discrete sampling, unaccounted-for additional model dynamics, actuators, and sensors.

Keywords

Variable structure systems · Relative degree · Discontinuous control · Robustness · Uncertainty · Filtering · Differentiation · Sampling · Noise · Homogeneity

Notation A binary operation $\diamond$ of two sets is defined as $A \diamond B = \{a \diamond b \mid a \in A, b \in B\}$, $a \diamond B = \{a\} \diamond B$. A function of a set is the set of function values on this set. $\mathbb{R}_+ = [0, \infty)$; $\lfloor a \rfloor^b = |a|^b \text{sign } a$, $\lfloor a \rfloor^0 = \text{sign } a$.

Introduction

Sliding mode control (SMC) systems, also called variable-structure systems, counteract uncertainties by keeping constraints in the permanent-switching mode called SM (Utkin 1992; Utkin et al. 2009; Slotine and Li 1991). For example, consider stabilizing the system

$$\ddot{x} = A(t, x, \dot{x}) + B(t, x, \dot{x})u, \quad x, u \in \mathbb{R}, \\ |A(t, x, \dot{x})| \leq 1, \quad B(t, x, \dot{x}) \in [1, 2].$$

**Sliding Mode Control:
Finite-Time Observation
and Regulation, Fig. 1**

Trajectories of (a) classic SMC, (b) quasi-continuous second-order SMC

a. Classic SMC

b. 2nd-order SMC

Any line in the phase plane $x, \dot{x}$ also has the meaning of a differential equation. Thus, keeping the trajectory on the line $\sigma = \dot{x} + x = 0$ in the SM $\sigma = 0$ asymptotically stabilizes the system. The corresponding control $u = -(2 + |\dot{x}|) \text{sign } \sigma$ is the classical SMC (Fig. 1a, Utkin 1992). Another option is to apply the control $u = -2 \frac{|\dot{x}|^2 + x}{\dot{x}^2 + |x|}$. It stabilizes x in finite time (FT) and is discontinuous only at $x = \dot{x} = 0$ keeping $x \equiv 0$ in the *second-order SM* (Fig. 1b, Ding et al. 2016).

Thus, the uncertainty has been completely removed by discontinuous control. Both controls utilize estimations of $\dot{x}$ for stabilizing x .

Basic Notions

Filippov definition Consider a differential equation (DE) $\dot{x} = v(t, x)$, $x \in \mathbb{R}^{n_x}$, where v is a locally essentially bounded Lebesgue-measurable function. Its Filippov solution is any locally absolutely continuous function $x(t)$ which almost everywhere satisfies $\dot{x} \in K_F[v](t, x)$, $K_F[v](t, x) = \bigcap_{\delta > 0} \bigcap_{\mu_L N = 0} \overline{\text{co}} v(t, O_\delta(x) \setminus N)$. Here μ_L is the Lebesgue measure, $O_\delta(x)$ is the δ -vicinity of x , and $\overline{\text{co}}(\cdot)$ denotes the convex closure operation.

Usually v is almost everywhere continuous. Then $K_F[v](t, x)$ is the convex closure of all possible limits of $v(t, y)$, obtained as continuity points (t, y) approach (t, x) . Filippov solutions can be considered as limit solutions produced

by various switching regularizations (Filippov 2013). All DEs are further understood in the Filippov sense.

Relative degree The relative-degree notion (Isidori 1995) is extended to the non-autonomous case by adding the fictitious equation $\dot{t} = 1$. For the simplicity in the following, we restrict ourselves to the single-input single-output (SISO) case.

Consider a smooth SISO system

$$\dot{x} = a(t, x) + b(t, x)u, \quad \sigma = \sigma(t, x), \quad (1)$$

where $x \in \mathbb{R}^{n_x}$, a, b , and σ are smooth functions, $u, \sigma(t, x) \in \mathbb{R}$. If r is the relative degree at the point (t_0, x_0) , then

$$\sigma^{(r)} = h(t, x) + g(t, x)u \quad (2)$$

holds for some smooth h, g , where the function $g(t, x)$ does not vanish in a vicinity of (t_0, x_0) . Relative-degree identification is often reduced to finding the shortest chain-rule differentiation way from σ to u and does not require the exact model knowledge.

In practice almost always $r = 2, 3, 4$, for engineers need a simple model. Significant parts of a real system are voluntarily moved to actuators and sensors or are simply ignored as insignificant functional and singular perturbations. Note that SMC systems are robust to such model perturbations (Levant and Livne 2016; Levant 2010).

Sliding mode Any Filippov solution lying on the discontinuity surface/set of a differential equation is said to be in SM. If a constraint $\sigma = 0$ is kept, the notation SM $\sigma = 0$ is used, and σ is called *the sliding variable* (Utkin 1992).

SM order Consider a SM $\sigma = 0$ in a closed-loop system. Let σ be a continuous scalar function. *The sliding order* k is the lowest k , such that the k th-order total time derivative $\sigma^{(k)}$ is not a continuous function of the state and time (Levant 2003; Shtessel et al. 2014). The corresponding motion $\sigma \equiv 0$ is called the k th-order SM or k -sliding mode (k -SM). In the case of a vector sliding variable σ also the sliding order is a vector.

Connection to the relative degree Consider system (1) with a scalar sliding variable σ of the relative degree r . Then, $\sigma, \dot{\sigma}, \dots, \sigma^{(r-1)}$ are continuous functions of t, x , i.e., the sliding order is never less than r .

In the control discontinuity case, the relative and the sliding order, the SM, and the zero dynamics coincide. In that case the function $u_{eq} = -h/g$, found from (2) and $\sigma^{(r)} = 0$, is traditionally called the *equivalent control* (Utkin 1992). The classic SMs (Slotine and Li 1991; Utkin 1992) (Fig. 1a) are based on the 1-SM $\sigma = 0$.

SMC completely removes *matched disturbances*. Indeed, let (1) have the form $\dot{x} = a(t, x) + b(t, x)(u + \xi(t, x))$. Then SM (zero) dynamics do not depend on ξ .

Chattering attenuation SMC can generate undesired system vibrations, called chattering (Boiko and Fridman 2005), which often are considered the main drawback of SMC. Replacing the relay function $\text{sign } \sigma$ with a “sigmoid” function, like $\sigma/(|\sigma| + \epsilon)$, $\epsilon > 0$, (Slotine and Li 1991), yields a system sensitive to uncertainties for finite ϵ and causes strong chattering due to small sampling noises for $\epsilon \ll 1$ (Levant 2010).

Another chattering-reduction method consists in inserting a number of integrators in the feedback (Bartolini et al. 1998; Shtessel et al. 2014). Suppose the relative degree is r . Then the virtual discontinuous control $u^{(l)}$ is applied to establish the $(r + l)$ -SM $\sigma = 0$. Correspondingly, $u, \dot{u}, \dots, u^{(l-1)}$ are formally included in the system state (Dorel and Levant 2008). Note that the chattering reduction is not due to the continuity of the resulting actual control $u(t)$, but due to simultaneously keeping $\sigma, \dot{\sigma}, \dots, \sigma^{(r+l-1)}$ at zero, while only $\sigma, \dot{\sigma}, \dots, \sigma^{(r-1)}$ are the physical plant coordinates (Levant 2010).

Finite-Time Output Regulation

SMC problem Consider system (1), (2) of the relative degree r , and assume that

$$|h(t, x)| \leq C, \quad 0 < K_m \leq g(t, x) \leq K_M. \quad (3)$$

Such assumption holds at least for any compact operational region. Each solution of (1) is assumed infinitely extendable in time, provided σ , its derivatives $\dot{\sigma}, \dots, \sigma^{(r-1)}$, and u remain bounded along the solution.

Due to the uncertainty of g, h , any feedback control $u = u(\sigma)$, $\sigma = (\sigma, \dot{\sigma}, \dots, \sigma^{(r-1)})$ is to be discontinuous. Such a control is called quasi-continuous (QC) if it is continuous at each $\sigma \neq 0$.

Consider an output-regulation/tracking problem. Let σ be the tracking error, and consider the problem of establishing the r -SM $\sigma = 0$ by a feedback $u(\sigma)$ in FT.

Homogeneous SMC

Uncertain dynamics (2) satisfy the concrete differential inclusion $\sigma^{(r)} \in [-C, C] + [K_m, K_M]u$. Most r -SM controllers are built as its FT stabilizers. Probably the simplest QC r -SMC has the form (Cruz-Zavala and Moreno 2017; Ding et al. 2016)

$$u = -\alpha \Psi_r(\sigma) = -\alpha \frac{|\sigma^{(r-1)}|^{\frac{\omega}{r}} + \beta_{r-2} |\sigma^{(r-2)}|^{\frac{\omega}{2}} + \dots + \beta_0 |\sigma|^{\frac{\omega}{r}}}{|\sigma^{(r-1)}|^{\frac{\omega}{r}} + \beta_{r-2} |\sigma^{(r-2)}|^{\frac{\omega}{2}} + \dots + \beta_0 |\sigma|^{\frac{\omega}{r}}}, \quad \omega > 0. \quad (4)$$

Theorem by Ding et al. (2016) states that for any $\omega > 0$, there exist such $\beta_0, \dots, \beta_{r-2} > 0$ that controller (4) stabilizes σ in FT for any sufficiently large $\alpha > 0$ only depending on K_m, K_M, C .

Functions $\Psi_r(\sigma)$ are invariant with respect to the transformation $\sigma^{(i)} \mapsto \kappa^{r-i} \sigma^{(i)}$,

$$\begin{aligned} r=1: u &= -\alpha \operatorname{sign} \sigma; & r=2: u &= -\alpha \frac{|\dot{\sigma}|^2 + \sigma}{\dot{\sigma}^2 + |\sigma|}; \\ r=3: u &= -\alpha \frac{\ddot{\sigma}^3 + 2|\dot{\sigma}|^{\frac{3}{2}} + \sigma}{|\ddot{\sigma}|^3 + 2|\dot{\sigma}|^{\frac{3}{2}} + |\sigma|}; & r=4: u &= -\alpha \frac{|\ddot{\sigma}|^4 + 2|\dot{\sigma}|^2 + 2|\dot{\sigma}|^{\frac{4}{3}} + \sigma}{\ddot{\sigma}^4 + 2\ddot{\sigma}^2 + 2\dot{\sigma}^{\frac{4}{3}} + |\sigma|}; \\ r=5: u &= -\alpha \frac{|\sigma^{(4)}|^5 + 6|\ddot{\sigma}|^{\frac{5}{2}} + 5|\ddot{\sigma}|^{\frac{5}{3}} + 3|\dot{\sigma}|^{\frac{5}{4}} + \sigma}{|\sigma^{(4)}|^5 + 6|\ddot{\sigma}|^{\frac{5}{2}} + 5|\ddot{\sigma}|^{\frac{5}{3}} + 3|\dot{\sigma}|^{\frac{5}{4}} + |\sigma|}. \end{aligned} \quad (5)$$

Differentiation and Filtering

Let $\operatorname{Lip}_n(L)$ be the set of all functions $\mathbb{R}_+ \rightarrow \mathbb{R}$, whose n th derivative has the Lipschitz constant $L > 0$. Assume that the sampled input signal $f(t)$, $f(t) = f_0(t) + \eta(t)$, consist of a Lebesgue-measurable noise $\eta(t)$ and an unknown basic signal $f_0(t)$, $f_0 \in \operatorname{Lip}_n(L)$. The noise η is bounded, $|\eta| \leq \varepsilon_0$. The number $\varepsilon_0 \geq 0$ is unknown.

Differentiation problem (Levant 2003) The problem is to estimate the derivatives $f_0^{(i)}(t)$, $i = 0, 1, \dots, n$, in real time by differentiator outputs $z_i(t)$. That estimation is to be exact in the absence of noises after some FT transient. The steady-state accuracies $\sup |z_i - f_0^{(i)}|$ are to continuously depend on ε_0 .

Asymptotically optimal differentiation Any differentiator exact on the input signals $f_0, f \in \operatorname{Lip}_n(L)$ has the worst-case steady-state accuracy $\sup |z_i - f_0^{(i)}| = 2^{\frac{i}{n+1}} K_{n,i} L^{\frac{i}{n+1}} \varepsilon_0^{\frac{n+1-i}{n+1}}$ for some f_0, f and $|f(t) - f_0(t)| \leq \varepsilon_0$ (Levant et al. 2017). Here $K_{n,i} \in [1, \pi/2]$ are the Kolmogorov constants (Kolmogoroff 1962), e.g., $K_{1,1} = \sqrt{2}$.

A differentiator is called *asymptotically optimal* (Levant et al. 2017; Levant and Yu 2018) if for some $\mu_i > 0$ the steady-state accuracy $\sup |z_i - f_0^{(i)}| \leq \mu_i L^{\frac{i}{n+1}} \varepsilon_0^{\frac{n+1-i}{n+1}}$ holds for any signal $f_0 \in \operatorname{Lip}_n(L)$ and any noise η , $|\eta(t)| \leq \varepsilon_0$, $i = 0, 1, \dots, n$.

$i = 0, 1, \dots, r-1$, $\kappa > 0$. Such controllers are called r -SM homogeneous (Levant and Livne 2016; Shtessel et al. 2014). Obviously, $|\Psi_r(\sigma)| \leq 1$, i.e., $|u| \leq \alpha$.

The following are valid controllers for $r = 1, 2, 3, 4, 5$, $\omega = r$:

Introduce the number $n_f \geq 0$ which is further called *the differentiator filtering order*. The **filtering differentiator** (Levant and Yu 2018; Levant and Livne 2019) has the form

$$\begin{aligned} \dot{w}_1 &= -\tilde{\lambda}_{n+n_f} L^{\frac{1}{n+n_f+1}} [w_1]^{\frac{n+n_f}{n+n_f+1}} + w_2, \\ &\dots \\ \dot{w}_{n_f-1} &= -\tilde{\lambda}_{n+2} L^{\frac{n_f-1}{n+n_f+1}} [w_1]^{\frac{n+2}{n+n_f+1}} + w_{n_f}, \\ \dot{w}_{n_f} &= -\tilde{\lambda}_{n+1} L^{\frac{n_f}{n+n_f+1}} [w_1]^{\frac{n+1}{n+n_f+1}} + z_0 - f(t), \\ \dot{z}_0 &= -\tilde{\lambda}_n L^{\frac{n_f+1}{n+n_f+1}} [w_1]^{\frac{n}{n+n_f+1}} + z_1, \\ &\dots \\ \dot{z}_{n-1} &= -\tilde{\lambda}_1 L^{\frac{n+n_f}{n+n_f+1}} [w_1]^{\frac{1}{n+n_f+1}} + z_n, \\ \dot{z}_n &= -\tilde{\lambda}_0 L \operatorname{sign}(w_1). \end{aligned} \quad (6)$$

In the case $n_f = 0$ the first n_f equations (6) disappear, and $w_1 = z_0 - f(t)$ is formally substituted for w_1 yielding the well-known differentiator by Levant (2003). In the case $n = 0$ only the equation for z_0 remains in the lower part (7).

Parameters $\tilde{\lambda}_i$ are most easily found using the parameters $\lambda_0, \dots, \lambda_p$, $p = n + n_f$, of the differentiator recursive form (Levant et al. 2017; Levant 2003): $\tilde{\lambda}_0 = \lambda_0$, $\tilde{\lambda}_p = \lambda_p$, and $\tilde{\lambda}_j = \lambda_j \tilde{\lambda}_{j+1}^{j/(j+1)}$, $j = p-1, p-2, \dots, 1$. An infinite sequence of parameters $\lambda = \{\lambda_0, \lambda_1, \dots\}$ can be

Sliding Mode Control: Finite-Time Observation and Regulation, Table 1 Parameters $\tilde{\lambda}_0, \tilde{\lambda}_1, \dots, \tilde{\lambda}_{n+n_f}$ of differentiator (6), (7) for $n + n_f = 0, 1, \dots, 7$

0	1.1							
1	1.1	1.5						
2	1.1	2.12	2					
3	1.1	3.06	4.16	3				
4	1.1	4.57	9.30	10.03	5			
5	1.1	6.75	20.26	32.24	23.72	7		
6	1.1	9.91	43.65	101.96	110.08	47.69	10	
7	1.1	14.13	88.78	295.74	455.40	281.37	84.14	12

built (Levant 2003), providing coefficients $\tilde{\lambda}_i$ of (6), (7) for all $n, n_f \geq 0$. In particular, $\lambda = \{1.1, 1.5, 2, 3, 5, 7, 10, 12, \dots\}$ suffice for $n + n_f \leq 7$ (Levant et al. 2017). The corresponding parameters $\tilde{\lambda}_i$ are listed in Table 1.

For brevity denote (6), (7) by

$$\dot{w} = \Omega_{n,n_f}(w, z_0 - f, L), \quad \dot{z} = D_{n,n_f}(w_1, z, L), \quad (8)$$

with the tracking difference $z_0(t) - f(t)$ singled out as a separate argument.

Extend the above conditions on the input by letting the noise have the form $\eta(t) = \eta_0(t) + \eta_1(t) + \dots + \eta_{n_f}(t)$, where each η_k , $k = 0, \dots, n_f$, is a Lebesgue-measurable locally-integrable signal. For each k there exists a uniformly bounded solution $\xi_k(t)$ of the equation $\dot{\xi}^{(k)} = \eta_k$, $|\xi(t)| \leq \varepsilon_k$. Though $\eta_1, \dots, \eta_{n_f}$ are possibly unbounded, they can be described as being small in the average.

The differentiator in FT provides the accuracy

$$|z_i(t) - f_0^{(i)}(t)| \leq \mu_i L \rho^{n+1-i}, \quad i = 0, 1, \dots, n, \\ \rho = \max \left[\left(\frac{\varepsilon_0}{L} \right)^{1/(n+1)}, \dots, \left(\frac{\varepsilon_{n_f}}{L} \right)^{1/(n+n_f+1)} \right] \quad (9)$$

for some $\mu_i > 0$ only depending on the parameters $\tilde{\lambda}_0, \dots, \tilde{\lambda}_{n+n_f}$ (Levant and Livne 2019).

Taking $\eta_1, \dots, \eta_{n_f} = 0$, obtain that differentiator (6), (7) is asymptotically optimal. Moreover, it is also applicable in the case when the noise components η_k are only small in average on any *finite* time interval not exceeding some $T_k > 0$ in its length (Levant and Livne 2019). The error dynamics of the differentiator is homogeneous (Levant and Livne 2019).

Homogeneous Output Feedback SMC

The stated SMC problem of the FT exact stabilization of σ is solved by the output feedback SMC

$$\begin{aligned} \dot{w} &= \Omega_{r-1,n_f}(w, z_0 - \sigma, L), \\ \dot{z} &= D_{r-1,n_f}(w_1, z, L), \\ u &= -\alpha \Psi(z), \quad L \geq C + K_M \alpha \end{aligned} \quad (10)$$

for any filtering order $n_f \geq 0$. The proof is trivial, since $\sigma \in \text{Lip}_{r-1}(L)$.

Let the sliding variable be sampled with the same noise $\eta(t) = \eta_0(t) + \eta_1(t) + \dots + \eta_{n_f}(t)$ as above. Then for any sufficiently large $\alpha > 0$, control (10) in FT provides for the accuracy

$$|\sigma_0^{(i)}(t)| \leq \tilde{\mu}_i \rho^{r-i}, \quad i = 0, 1, \dots, r-1, \\ \rho = \max \left[\left(\frac{\varepsilon_0}{L} \right)^{1/r}, \dots, \left(\frac{\varepsilon_{n_f}}{L} \right)^{1/(r+n_f)} \right] \quad (11)$$

for some $\tilde{\mu}_i > 0$ only depending on the parameters $\tilde{\lambda}_0, \dots, \tilde{\lambda}_{n+n_f}, L, \alpha, C, K_m, K_M$.

Note that the bound L can be very rough (50–100 times larger than needed), and the knowledge of C, K_m, K_M is not really required, since the control parameter α is usually found by simulation.

Discretization

In reality the system evolves in the continuous time, whereas the sampling and the control injection are performed at discrete times. Correspondingly, the differentiator dynamics are replaced with some numeric integration of (8).

Let the input be sampled at the times $t_0, t_1, \dots, t_k \rightarrow \infty, \tau_k = t_{k+1} - t_k > 0, \tau_k \leq \tau$.

Discretization of the output-feedback control (10) is done by the one-step Euler method with u and z kept constant over each sampling interval. In that case the accuracy (11) is preserved for $\rho = \max[(\varepsilon/L)^{1/r}, \tau]$ with possibly changed coefficients $\tilde{\mu}_i$, provided $\eta_1(t) + \dots + \eta_{n_f}(t) \equiv 0$, i.e., only η_0 is present (Levant and Livne 2015). The general-case formula is more complicated and is omitted here (Levant and Livne 2019).

The stand-alone discretization of the differentiator (8) takes the form (Levant and Livne 2019)

$$\begin{aligned} w(t_{k+1}) &= w(t_k) + \mathcal{Q}_{n,n_f}(w(t_k), z_0(t_k) - f(t_k), L)\tau_k, \\ z(t_{k+1}) &= z(t_k) + D_{n,n_f}(w_1(t_k), z(t_k), L)\tau_k + H_n(z(t_k), \tau_k), \\ H_n(z(t_k), \tau_k) &= (H_{n,0}, \dots, H_{n,n})^T, \quad H_{n,n-1} = H_{n,n} = 0, \\ H_{n,i} &= \frac{1}{2!}z_{i+2}(t_k)\tau_k^2 + \dots + \frac{1}{(n-i)!}z_n(t_k)\tau_k^{n-i}, \quad i = 0, 1, \dots, n-2. \end{aligned} \quad (12)$$

The Taylor-like terms H_n are required only to improve the accuracy with respect to τ in the presence of very small noises (Livne and Levant 2014). Also here formula (9) remains true when only the noise η_0 is present and $\rho = \max[(\varepsilon/L)^{1/n+1}, \tau]$. The general formula is more complicated (Levant and Livne 2019).

Examples

Numeric differentiation Consider the sampled signal

$$\begin{aligned} f(t) &= f_0(t) + \eta(t), \\ f_0(t) &= 0.5 \sin t + 0.8 \cos(0.8t), \end{aligned} \quad (13)$$

where $\eta(t)$ is the noise. Let the sampling interval be constant, $\tau_k = \tau$. The filtering differentiator (12) of the order $n = 5$ and the filtering order 2 is applied with $L = 1$, $\tau = 10^{-4}$, and $z(0) = 0$, $w(0) = 0$. Obviously $|f_0^{(6)}| \leq L$. The coefficients are taken from Table 1 from row 7, $7 = 5 + 2$.

Performance of the differentiator for $\eta = 0$ is demonstrated in Fig. 2a. Denote $|\Sigma|_{5,2} = (|w_1|, |w_2|, |z_0 - f_0|, \dots, |z_5 - f_0^{(5)}|)$. The differentiation accuracy for $t \in [10, 20]$ is provided by the component-wise inequality $|\Sigma|_{5,2} \leq (3.0 \cdot 10^{-23}, 2.4 \cdot 10^{-19}, 1.3 \cdot 10^{-15}, 1.4 \cdot 10^{-12}, 1.2 \cdot 10^{-9}, 5.1 \cdot 10^{-7}, 1.1 \cdot 10^{-4}, 0.012)$. This accuracy is practically the best one which can be obtained in the presence of the digital round-up errors due to the standard double-precision number format (Levant et al. 2017).

Consider the noise $\eta(t) = 3 \cos(10000t) - 6 \sin(20000t) - 4 \cos(70000t) + \eta_G(t)$, $\eta_G \in N(0, 0.1^2)$, where $\eta_G(t)$ is a Gaussian signal with the standard deviation 0.1. The corresponding performance of the same differentiator appears in Fig. 2b. The accuracy is $|\Sigma|_{5,2} \leq (1.2 \cdot 10^{-5}, 1.8 \cdot 10^{-3}, 0.015, 0.14, 0.60, 1.4, 1.9, 1.1)$.

Car control Consider a simple “bicycle” kinematic car model (Rajamani 2005)

$$\dot{x} = V \cos(\varphi), \quad \dot{y} = V \sin(\varphi), \quad \dot{\varphi} = \frac{V}{\Delta} \tan \theta, \quad \dot{\theta} = u, \quad (14)$$

where x and y are the Cartesian coordinates of the middle point of the rear axle (Fig. 3a), $\Delta = 5m$ is the distance between the two axles, φ is the orientation angle, $V = 10m/s$ is the constant longitudinal velocity, θ is the steering angle (i.e., the actual input), and $u = \dot{\theta}$ is the control.

The goal is to move along the trajectory $(x(t), y(t)) = (x(t), g(t))$, whereas $g(t), y(t)$ are sampled in real time. Correspondingly, introduce the sliding variable $\sigma = y(t) - g(t)$ sampled with the time step τ and a noise $\eta(t)$. Let $g(t) = 10 \sin(0.05x(t)) + 5$.

Obviously, $\dot{x}, \dot{y}$ contain φ , $\dot{\varphi}$ contains θ , and $\dot{\theta} = u$. Thus, the relative degree is 3. Apply the standard 3-SM controller (10), (5) for $r = 3$, $n_f = 2$, $L = 50$, $\alpha = 0.5$. Parameters α, L are found by simulation. The second-order differentiator starts at $t = 0$; the control is applied from $t = 1$ to $t = 40$. The integration is

Sliding Mode Control: Finite-Time Observation and Regulation, Fig. 2 Performance of differentiator (12) with $n = 5$, $n_f = 2$, $L = 1$ for $\tau = 10^{-5}$ and input (13):

(a) there is no noise; (b) performance for noisy sampling (only estimations of f_0 , $\dot{f}_0$, $\ddot{f}_0$ are shown)

Sliding Mode Control: Finite-Time Observation and Regulation, Fig. 3

Performance of the 3-SM car control (10) for $r = 3$, $n_f = 2$, $L = 50$, $\alpha = 0.5$, and the integration/sampling step $\tau = 10^{-5}$: (a) car model; (b) the required and the resulting trajectories; (c) steering angle; (d) control

performed by the Euler method with the time step $10^{-5}s$ (MatLab ODE solvers are not applicable).

First consider the case of the exact measurements, $\eta = 0$, $\tau = 10^{-5}s$. The corresponding performance is shown in Fig. 3. The SM accuracy $|\sigma| \leq 1.1 \cdot 10^{-12}m$, $|\dot{\sigma}| \leq 1.3 \cdot 10^{-5}m/s$, $|\ddot{\sigma}| \leq 0.002m/s^2$ is maintained.

Now introduce the sampling noise $\eta(t) = 2\cos(10000t) + \eta_G(t)$, $\eta_G \in N(0, 0.5^2)$ (Fig. 4c). The corresponding performance is shown in Fig. 4. The SM accuracy $|\sigma| \leq 0.041m$, $|\dot{\sigma}| \leq 0.67m/s$, $|\ddot{\sigma}| \leq 5.2m/s^2$ is maintained for the sampling step $\tau = 10^{-5}$ (Fig. 4a). The accuracy deteriorates for the sampling step $\tau = 0.01s$ to $|\sigma| \leq 2.8m$, $|\dot{\sigma}| \leq 2.7m/s$, $|\ddot{\sigma}| \leq 6.8m/s^2$ (Fig. 4b,d). The performance is still quite acceptable.

Summary and Future Directions

Multi-input multi-output regulation problem is solvable provided some rough approximation of the high-frequency gain matrix (Isidori 1995) is available (Defoort et al. 2009; Levant and Shustin 2018). Non-minimum phase SMC remains a long-standing challenge.

SMC contours are easily incorporated in control systems due to their accuracy and robustness, FT convergence, and the control smoothness option. In particular, SM observers and filters are capable of replacing expensive sensors in practical applications and linear filters in signal processing. Parameter L can be variable (Levant et al. 2017).

SMC systems are robust to noises, delays, singular and regular perturbations, and even to

Sliding Mode Control: Finite-Time Observation and Regulation, Fig. 4

Performance of the 3-SM car control (10) for $r = 3$, $n_f = 2$, $L = 50$, $\alpha = 0.5$, for the noisy sampling with the step τ : (a) trajectory for $\tau = 10^{-5}$ s; (b) trajectory for $\tau = 0.01$ s; (c) the noise; (d) steering angle for $\tau = 0.01$ s

relative-degree fluctuations (Levant 2010; Levant and Livne 2016). The practical relative degree approach (Shtessel et al. 2014) is expected to solve numerous problems with non-existing or large relative degrees or even without a reliable model.

Integral SMs (Utkin et al. 2009) remove the transient to SM. The Lyapunov-based homogeneous SM control and observation (Bernuau et al. 2014; Cruz-Zavala and Moreno 2016, Cruz-Zavala and Moreno 2017) is capable of fixed-time convergence (Angulo et al. 2013; Polyakov et al. 2015). Alternative SMC discretization strategies by Acary et al. (2012) reduce the chattering and improve the accuracy. Discrete SMs are considered by Furuta (1990), Bartoszewicz (1998) and Gao et al. (1995). SMC of infinite-dimensional systems is considered by Orlov (2008).

Small Phase Theorem

Wei Chen, Dan Wang, and Li Qiu

Department of Electronic and Computer Engineering, Hong Kong University of Science and Technology, Kowloon, Hong Kong, China

Abstract

The small gain theorem is one of the most important results in the theory of robust control. It lays the foundation for the traditional gain-based analysis and synthesis, especially within the $\mathcal{H}_\infty$ control paradigm. This entry is concerned with the small phase theorem, which can be regarded as a fitting counterpart to the small gain theorem. With the aid of a suitable definition of complex matrix phases, small phase results for matrices and linear time-invariant (LTI) systems are described. Together, they pave the way for a comprehensive theory of phases of complex systems.

Matrix phases · Phase response · Matrix small phase theorem · LTI small phase theorem

Introduction

In classical frequency domain analysis of single-input-single-output (SISO) systems, the magnitude (gain) response and phase response go hand in hand. The broad-ranging research into the multi-input-multi-output (MIMO) systems theory over the past several decades has elevated the concept of magnitude to a great height. In particular, the small gain theorem has come about as one of the most significant milestones in robust control theory, and it underpins the development of the celebrated $\mathcal{H}_\infty$ control. In contrast, a widely accepted parallel small phase theorem has been all but lacking for more than half a century. One main reason is that while the magnitudes of a complex matrix are commonly characterized by

its singular values, it is not until recently that a suitable definition of phase(s) of a complex matrix has been discovered.

This entry describes small phase theorems for matrices and LTI systems, based on the definition of phases of a complex matrix in Furtado and Johnson (2001) and Wang et al (2020). They open the door to a complete phase theory of complex systems.

Phases of a Complex Matrix

It is well understood that an $n \times n$ complex matrix C has n magnitudes, served by the n singular values $\sigma(C) = [\sigma_1(C) \ \sigma_2(C) \ \dots \ \sigma_n(C)]$ with $\bar{\sigma}(C) = \sigma_1(C) \geq \sigma_2(C) \geq \dots \geq \sigma_n(C) = \underline{\sigma}(C)$. The magnitudes of a matrix possess plentiful nice properties, among which the following majorization inequality is of particular interest to the control community.

Given $x, y \in \mathbb{R}^n$, denote by $x^\downarrow$ and $y^\downarrow$ the rearranged versions of x and y so that their elements are sorted in a non-increasing order. Then, x is said to be *majorized* by y , denoted by $x \prec y$, if $\sum_{i=1}^k x_i^\downarrow \leq \sum_{i=1}^k y_i^\downarrow$, $k = 1, \dots, n-1$, and $\sum_{i=1}^n x_i^\downarrow = \sum_{i=1}^n y_i^\downarrow$. When x and y are nonnegative, x is said to be *log-majorized* by y , denoted by $x \prec_{\log} y$, if $\prod_{i=1}^k x_i^\downarrow \leq \prod_{i=1}^k y_i^\downarrow$, $k = 1, \dots, n-1$, and $\prod_{i=1}^n x_i^\downarrow = \prod_{i=1}^n y_i^\downarrow$. The magnitudes of a matrix product satisfy (Marshall et al 2011)

$$\sigma(AB) \prec_{\log} \sigma(A) \odot \sigma(B), \quad (1)$$

where $\odot$ denotes the Hadamard product, i.e., the elementwise product.

An early attempt in Postlethwaite et al (1981) defined the phases of C as the complex arguments of the eigenvalues of the unitary part of its polar decomposition. However, phases defined this way do not enjoy certain desired properties.

A more appropriate definition of matrix phases that is naturally amenable to small phase type robustness analysis is one that is based on numerical range (Furtado and Johnson 2001; Wang et al 2020). The numerical range, also called field of

values, of a matrix $C \in \mathbb{C}^{n \times n}$ is defined as $W(C) = \{x^* C x : x \in \mathbb{C}^n \text{ with } \|x\| = 1\}$, which, as a subset of $\mathbb{C}$, is compact and convex and contains the spectrum of C .

If $0 \notin W(C)$, then $W(C)$ is in an open half complex plane. In this case, C is said to be a sectorial matrix which admits a sectorial decomposition $C = T^* D T$, where T is nonsingular and D is a diagonal unitary matrix that is unique up to a permutation (Horn and Steinberg 1959; Zhang 2015). The phases of C , denoted by $\bar{\phi}(C) = \phi_1(C) \geq \phi_2(C) \geq \dots \geq \phi_n(C) = \underline{\phi}(C)$, are defined to be the complex arguments of the eigenvalues of D so that $\bar{\phi}(C) - \underline{\phi}(C) < \pi$ and $\gamma(C) = \frac{\bar{\phi}(C) + \underline{\phi}(C)}{2}$, called the phase center of C , lies in $(-\pi, \pi]$. Define $\phi(C) = [\phi_1(C) \ \phi_2(C) \ \dots \ \phi_n(C)]$.

A graphical interpretation of the phases of a matrix C is provided in Fig. 1. The two angles from the positive real axis to each of the two supporting rays of $W(C)$ extending from the origin are $\bar{\phi}(C)$ and $\underline{\phi}(C)$, respectively. The other phases of C lie in between.

A naive analogy of the inequality (1) would hint at $\phi(AB) \prec \phi(A) + \phi(B)$. This, unfortunately, fails to hold even for positive definite A and B . Notwithstanding, if we consider instead $\lambda(AB) = [\lambda_1(AB) \ \dots \ \lambda_n(AB)]$, i.e., the vector of eigenvalues of AB , the following weaker but useful result can be derived (Ballantine and Johnson 1975; Wang et al 2020).

Small Phase Theorem, Fig. 1 A geometric interpretation of $\bar{\phi}(C)$ and $\underline{\phi}(C)$

Theorem 1 Let $A, B \in \mathbb{C}^{n \times n}$ be sectorial, and $\angle \lambda(AB)$ take values in $(\gamma(A) + \gamma(B) - \pi, \gamma(A) + \gamma(B) + \pi)$. Then $\angle \lambda(AB) \prec \phi(A) + \phi(B)$.

Matrix Small Phase Theorem

The singularity of the matrix $I + AB$ plays an important role in the stability analysis of feedback systems. The gain majorization relation (1) underpins the well-known matrix small gain theorem: If $\bar{\sigma}(A)\bar{\sigma}(B) < 1$, then $I + AB$ is nonsingular (Stewart and Sun 1990).

As for a counterpart, we have the following matrix small phase theorem (Wang et al 2020) that is underlied by the phase majorization relation in Theorem 1.

Theorem 2 (Matrix small phase theorem) If $\bar{\phi}(A) + \bar{\phi}(B) < \pi$ and $\underline{\phi}(A) + \underline{\phi}(B) > -\pi$, then $I + AB$ is nonsingular.

It is also known that the matrix small gain theorem is necessary in the following sense: For a given matrix A , there exists a matrix B satisfying $\bar{\sigma}(A)\bar{\sigma}(B) = 1$ such that $I + AB$ loses rank. In the same spirit, the above matrix small phase theorem is necessary in the following sense: For a given matrix A , there exists a matrix B satisfying $\bar{\phi}(A) + \bar{\phi}(B) = \pi$ or $\underline{\phi}(A) + \underline{\phi}(B) = -\pi$ such that $I + AB$ loses rank.

Phase Response of a MIMO LTI System

Let G be an $m \times m$ real rational proper stable transfer matrix, i.e., $G \in \mathcal{RH}_\infty^{m \times m}$. Then $\sigma(G(j\omega))$, the vector of singular values of $G(j\omega)$, is an $\mathbb{R}^m$ -valued function of the frequency, which we call the *magnitude response* of G . The $\mathcal{H}_\infty$ norm of G , defined by $\|G\|_\infty = \sup_{\omega \in \mathbb{R}} \bar{\sigma}(G(j\omega))$, is of particular importance.

Suppose $G(j\omega)$ is sectorial for all $\omega \in [0, \infty]$. Such a system is called a frequency-wise sectorial system. Also, assume for simplicity that $W(G(j\omega))$ does not intersect the negative real axis for all $\omega \in [0, \infty]$. Then $\phi(G(j\omega))$, the vector of phases of $G(j\omega)$ with each element taking values in $(-\pi, \pi)$, is well defined as an

$\mathbb{R}^m$ -valued function of the frequency, which we call the *phase response* of G . We define the $\mathcal{H}_\infty$ phase of G , as the counterpart to its $\mathcal{H}_\infty$ norm, to be $\Phi_\infty(G) = \sup_{\omega \in \mathbb{R}} \bar{\phi}(G(j\omega))$. Clearly, $\Phi_\infty(G) \leq \pi$. By plotting $\sigma(G(j\omega))$ and $\phi(G(j\omega))$ side by side, we have the MIMO Bode plot of G .

The notion of phase of MIMO LTI systems provides a means to unify the concepts of positive real systems and negative imaginary systems, in addition to generalizing the SISO system phase and much more. For instance, $G \in \mathcal{RH}_\infty^{m \times m}$ is said to be strongly positive real if $G(j\omega) + G^*(j\omega) > 0$ for all $\omega \in [0, \infty]$ (Liu and Yao 2016). In the language of phase, this is equivalent to $\Phi_\infty(G) < \frac{\pi}{2}$.

LTI Small Phase Theorem

Suppose $G, H \in \mathcal{RH}_\infty^{m \times m}$. The feedback interconnection of G and H , as depicted in Fig. 2, is said to be stable if the gang of four matrix

$$G\#H = \begin{bmatrix} (I + HG)^{-1} & (I + HG)^{-1}H \\ G(I + HG)^{-1} & G(I + HG)^{-1}H \end{bmatrix}$$

is stable, i.e., $G\#H \in \mathcal{RH}_\infty^{2m \times 2m}$.

A version of the famous small gain theorem states that if $\bar{\sigma}(G(j\omega))\bar{\sigma}(H(j\omega)) < 1$ for all $\omega \in \mathbb{R}$, then $G\#H$ is stable (Zhou et al 1996). As its counterpart, the small phase theorem (Chen et al 2019) is in order.

Theorem 3 (LTI small phase theorem) If $\bar{\phi}(G(j\omega)) + \bar{\phi}(H(j\omega)) < \pi$ for all $\omega \in \mathbb{R}$, then $G\#H$ is stable.

Small Phase Theorem, Fig. 2 A standard feedback system

The small phase theorem generalizes a stronger version of the passivity theorem, which states that $G\#H$ is stable if both G and H are strongly positive real (Liu and Yao 2016).

Note that the small gain theorem provides a quantifiable tradeoff between the gains of G and H , while the above small phase theorem does the same with respect to the phases of G and H . In early literature, the notions of input feedforward passivity index and output feedback passivity index (Bao and Lee 2007; Kottenstette et al 2014; Vidyasagar 1981; Wen 1988) have been used to characterize the tradeoff between the surplus and deficit of passivity in open-loop systems. The concept of MIMO system phases provides an alternative that may be even more suited to this task. Specifically, $\frac{\pi}{2} - \Phi_{\infty}(G)$ gives a natural measure of passivity of system G , which we call the *angular passivity index*. The small phase theorem above indicates that if the sum of the angular passivity indexes of G and H are positive, then $G\#H$ is stable. In addition, $\pi - \Phi_{\infty}(GH)$ yields a natural phase margin for a stable $G\#H$.

It is known that the LTI small gain theorem is necessary in the following sense. Let $r \in \mathcal{RH}_{\infty}$ be a scalar transfer function and define a ball of systems

$$\mathcal{B}(r) = \left\{ H \in \mathcal{RH}_{\infty} : \overline{\sigma}(H(j\omega)) < |r(j\omega)| \text{ for all } \omega \in \overline{\mathbb{R}} \right\}.$$

Then, $G\#H$ is stable for all $H \in \mathcal{B}(r)$ if and only if $\overline{\sigma}(G(j\omega)) \leq \frac{1}{|r(j\omega)|}$ for all $\omega \in \mathbb{R}$. Analogously, the above LTI small phase theorem is necessary in the following sense. Let $h \in \mathcal{RH}_{\infty}$ be a scalar strongly positive real function and define a cone of systems

$$\mathcal{C}(h) = \left\{ H \in \mathcal{RH}_{\infty} : \overline{\phi}(H(j\omega)) < \pi/2 + \angle h(j\omega) \text{ for all } \omega \in \overline{\mathbb{R}} \right\}.$$

Then, $G\#H$ is stable for all $H \in \mathcal{C}(h)$ if and only if $\overline{\phi}(G(j\omega)) \leq \pi/2 - \angle h(j\omega)$ for all $\omega \in \mathbb{R}$.

Summary and Future Directions

Small phase theorem kicks off an exciting journey of developing a comprehensive phase theory of complex systems, complementing the existing gain-based system and control theory. A sectorized real lemma (a phasic counterpart to the bounded real lemma) can be found in Chen et al (2019), which gives a state space characterization of phase-bounded MIMO LTI systems in terms of linear matrix inequalities. The implications of small phase theorem in large-scale dynamical networks are worth the investigation. Similar to the fact that the small gain theorem nurtured the celebrated $\mathcal{H}_{\infty}$ norm optimal control, the small phase theorem is expected to cultivate an $\mathcal{H}_{\infty}$ phase optimal control theory, which opens up a vast space for future research.

Some preliminary studies indicate that extending the phase concept to nonlinear systems is a promising direction. How does one define the phase of a nonlinear system in a meaningful manner? How is it related to the classical Lyapunov approach? Can one formulate a nonlinear small phase theorem? Studying these questions and many others will lead to a powerful nonlinear system phase theory.

Gain and phase not only complement each other, but they also interact intimately. When they are integrated, miracles ensue. Understanding their exact relations and eventually coming up with a combined gain/phase theory will have a profound impact in the evolution of system and control theory.

Recommended Reading

For more details on the newest developments of matrix phases, one can refer to Wang et al (2020), where a collection of properties of matrix phases are studied and the matrix small phase theorem

is provided. Earlier explorations of matrix phases and sectorial matrices can be found in Ballantine and Johnson (1975); Furtado and Johnson (2001); Arlinskiĭ and Popov (2003); Zhang (2015); Horn and Steinberg (1959); Horn and Johnson (1991).

The phase response of a MIMO system and the LTI small phase theorem are detailed in Chen et al (2019). The concept of phase has a great potential for unifying the notions of positive real systems, passive systems, negative imaginary systems, and counterclockwise dynamics, on which the representative works include Bao and Lee (2007), Wen (1988), Kottenstette et al (2014), Lanzon and Petersen (2008), Mabrok et al (2015), and Angeli (2006). The results described in this article are closely related to the theory of integral quadratic constraints and the (generalized) KYP lemma. See the seminal papers Iwasaki and Hara (1998, 2005) and the recent work in Khong and Kao (2019).

Small Signal Stability in Electric Power Systems

Vijay Vittal

Arizona State University, Tempe, AZ, USA

Abstract

Small signal rotor angle stability analysis in power systems is associated with insufficient damping of oscillations under small disturbances. Rotor angle oscillations due to insufficient damping have been observed in many power systems around the world. This entry overviews the predominant approach to examine small signal rotor angle stability in large power systems using eigenvalue analysis.

Keywords

Eigenvalues · Eigenvectors · Low-frequency oscillations · Mode shape · Oscillatory modes · Participation factors · Small signal rotor angle stability

Small Signal Rotor Angle Stability in Power Systems

As power system interconnections grew in number and size, automatic controls such as voltage regulators played critical roles in enhancing reliability by increasing the synchronizing capability between the interconnected systems. As technology evolved the capabilities of voltage regulators to provide synchronizing torque following disturbances were significantly enhanced. It was, however, observed that voltage regulators tended to reduce damping torque, as a result of which the system was susceptible to rotor angle oscillatory instability. An excellent exposition of the mechanism and the underlying analysis is provided in the textbooks (Anderson and Fouad 2003; Sauer and Pai 1998; Kundur 1993), and a number of practical aspects of the analysis are detailed in Eigenanalysis and Frequency Domain Methods for System Dynamic Performance (1989) and Rogers (2000). Two types of rotor angle oscillations are commonly observed. Low-frequency oscillations involving synchronous machines in different operating areas are commonly referred to as inter-area oscillations. These oscillations are typically in the 0.1–2 Hz frequency range. Oscillations between local machines or a group of machines at a power plant are referred to as plant mode oscillations. These oscillations are typically above the 2 Hz frequency range. The modes associated with rotor angle oscillations are also termed inertial modes of oscillation. Other modes of oscillations associated with the various controls also exist. With the integration of significant new wind and photovoltaic generation which are interconnected to the grid using converters, new modes of oscillation involving the converter controls and conventional synchronous generator states are being observed.

The basis for small signal rotor angle stability analysis is that the disturbances considered are small enough to justify the use of linear analysis to examine stability (Kundur et al. 2004). As a result, Lyapunov's first method Vidyasagar (1993) provides the analytical underpinning to analyze small signal stability. Eigenvalue analysis is the predominant approach to analyze small signal rotor angle stability in power systems. Commercial software packages that utilize sophisticated algorithms to analyze large-scale power systems with the ability to handle detailed models of power system components exist.

The power system representation is described by a set of nonlinear differential algebraic equations shown in (1)

$$\begin{aligned}\dot{x} &= f(x, z) \\ 0 &= g(x, z)\end{aligned}\quad (1)$$

where x is the state vector and z is a vector of algebraic variables. Small signal stability analysis involves the linearization of (1) around a system operating point which is typically determined by conducting a power flow analysis:

$$\begin{bmatrix} \Delta \dot{x} \\ 0 \end{bmatrix} = \begin{bmatrix} J_1 & J_2 \\ J_3 & J_4 \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta z \end{bmatrix}\quad (2)$$

The power system state matrix can be obtained by eliminating the vector of algebraic variables Δz in (2)

$$\Delta \dot{x} = (J_1 - J_2 J_4^{-1} J_3) \Delta x = A \Delta x \quad (3)$$

where A represents the system state matrix. Based on Lyapunov's first method, the eigenvalues of A characterize the small signal stability behavior of the nonlinear system in a neighborhood of the operating point around which the system is linearized. The eigenvectors corresponding to the eigenvalues also provide significant qualitative information. For each eigenvalue λ_i , there exists a vector u_i known as the right eigenvector of A which satisfies the equation

$$A u_i = \lambda_i u_i \quad (4)$$

There also exists a row vector v_i known as the left eigenvector of A which satisfies

$$v_i A = \lambda_i v_i \quad (5)$$

For a system which has distinct eigenvalues, the right and left eigenvectors form an orthogonal set governed by

$$\begin{aligned} v_i u_j &= k_{ij} \\ \text{where} \\ k_{ij} &\neq 0 \quad i = j \\ k_{ij} &= 0 \quad i \neq j \end{aligned} \quad (6)$$

One set (either right or left) of eigenvectors are usually scaled to unity and the other set obtained by solving (6) with $k_{ij} = 1$. The right eigenvectors can be assembled together as columns of a square matrix U , and the corresponding left eigenvectors can be assembled as rows of a matrix V ; then

$$V = U^{-1} \quad (7)$$

and

$$V A U = \Lambda \quad (8)$$

where Λ is a diagonal matrix with the distinct eigenvalues as the diagonal entries. The relationship in (8) is a similarity transformation and in the case of distinct eigenvalues provides a pathway to obtain solutions to the linear system of equations (3). Applying the following similarity transformation to (3)

$$\Delta x = U z \rightarrow \Delta x_i(t) = \sum_{j=1}^n u_{ij} z_j e^{\lambda_j t} \quad (9)$$

$$U \dot{z} = A U z \quad (10)$$

$$\dot{z} = U^{-1} A U z = V A U z = \Lambda z \quad (11)$$

$$\dot{z}_i(t) = \lambda_i z_i \Rightarrow z_i(t) = z_i(0) e^{\lambda_i t} \quad (12)$$

$$z_i(0) = v_i^T \Delta x(0) \quad (13)$$

$$z_i(t) = v_i^T \Delta x(0) e^{\lambda_i t} \quad (14)$$

From (9) and (14), it can be observed that the right eigenvector describes how each mode of the system is distributed throughout the state vector (and is referred to as the mode shape), and the left eigenvector in conjunction with the initial conditions of the system state vector determines the magnitude of the mode. The right eigenvector or the mode shape has been often used to identify dynamic patterns in small signal dynamics. One problem with the mode shape is that it is dependent on the units and scaling of the state variables as a result of which it is difficult to compare the magnitudes of entries that are disparate and correspond to states that impact the dynamics differently. This resulted in the development of the participation factors (Pérez-Arriaga et al. 1982) which are dimensionless and independent of the choice of units. The participation factor is expressed as

$$p_{ik} = v_{ik} u_{ik} \quad (15)$$

The magnitude of the participation factor measures the relative participation of the i th state variable in the k th mode and vice versa.

Small Signal Stability Analysis Tools for Large Power Systems

Efficient software tools exist that facilitate the application of the methods in section “[Small Signal Rotor Angle Stability in Power Systems](#)” to large power systems (Powertech 2012; Martins 1989). These tools incorporate detailed models of power system components and also leverage the sparsity in power systems. The building of the A matrix is a complex task for large power systems with a multitude of dynamic components. The approach in Powertech (2012) utilizes a technique where state space equations are developed for each dynamic component in the system using a solved power flow solution and the dynamic data description for a given system. These state space equations are then coupled based on the system topology, and the system A matrix is derived as in (3). Reference Martins (1989) takes advantage of the sparsity of the Jacobian matrix

in (2) and develops efficient algorithms to determine the eigenvalues and eigenvectors. The software tools also provide the flexibility of a number of different options with regard to eigenvalue computations:

1. Calculation of a specific eigenvalue at a specified frequency or with a specified damping ratio
2. Simultaneous calculation of a group of relevant eigenvalues in a specified frequency range or in specified damping ratio range

In addition to the features described above, commercial software packages also provide features to evaluate:

1. Frequency response plots
2. Participation factors
3. Transfer functions, residues, controllability, and observability factors
4. Linear time response to step changes
5. Eigenvalue sensitivities to changes in specified parameters

Applications of Small Signal Stability Analysis in Power Systems

Small signal stability analysis tools are used for a range of applications in power systems. These applications include:

Analysis of local stability problems – These types of stability problems are primarily associated with the tuning of control associated with the synchronous generator, converter interconnected renewable resources, and HVDC link current control. In certain cases analysis of local stability problems could also involve design of supplementary controllers which enhance the stability region. Since the stability problem pertains to a local portion of the power system, there is significant flexibility in modeling the system. In many instances local stability problems facilitate the use of a simple representation of a power system which could include the particular machine or

a local group of machines in question together with a highly equivalenced representation of the rest of the system. In cases where controls other than generator controls influence stability, e.g., static VAR compensators or HVDC links, the system representation would need to be extended to include portions of the system where these devices are located. Typical small signal stability problems that are analyzed include:

1. Power system stabilizer design
2. Automatic voltage regulator tuning
3. Governor tuning
4. DC link current control
5. Small signal stability analysis for subsynchronous resonance
6. Load modeling effects on small signal stability

References Eigenanalysis and Frequency Domain Methods for System Dynamic Performance (1989) and Rogers (2000) provide comprehensive examples of the analysis conducted for each of the problems listed above.

Analysis of global stability problems – These types of stability problems are associated with controls that impact generators located in different areas of the power systems. The analysis of these inter-area problems requires a more systematic approach and involves representation of the power system in greater detail. The problems that are analyzed under this category include:

1. Power system stabilizer design
2. HVDC link modulation
3. Static VAR compensator controls

References Eigenanalysis and Frequency Domain Methods for System Dynamic Performance (1989) and Rogers (2000) again provide details of the analysis conducted for each of the problems listed under this category.

Space Robotics

Marcello Romano
Department of Mechanical and Aerospace
Engineering, Naval Postgraduate School,
Monterey, CA, USA

Abstract

Space robotics enables humankind to pioneer the exploration and utilization of space. This article gives a general introduction to the science and technology of space robotics. First,

the article defines space robotics, introduces some fundamental concepts and lists its foundational disciplines. Then, a key mathematical model is presented. Finally, a survey of the state of the art is given, together with a perspective on future developments and pointers to additional information. This article was written as a self-contained introduction. It is directed at space science and engineering students, new space researchers and practitioners, as well as at a broader audience interested in astronautics.

Keywords

Astronautics · Orbital robotics · Planetary robotics

Introduction

Space robotics is defined as the science concerned with the study of engineering and operations of spacecraft systems that can *physically interact with another object in space* by using actively controlled onboard mechanisms that enable *manipulation* or *mobility*. In this definition, a spacecraft stands for a space vehicle that is either manned or unmanned. That space vehicle can be either orbiting a celestial body (Earth, Moon, Sun, or other Solar System planets, moons, asteroids, and comets) – and in this case is also referred to as an artificial satellite – or operating on the surface of an extraterrestrial celestial body.

Space robotics can be further divided into two large subcategories:

Orbital robotics, a.k.a. Microgravity Robotics, is concerned with orbiting space robotic systems: a paradigmatic example is an artificial satellite equipped with an onboard robotic manipulator that enables grasping and manipulating other orbiting objects for servicing, assembly of space stations or other large structures, and removal of orbital debris.

Planetary robotics is concerned with space robotic systems operating on the surface of an extraterrestrial body: a paradigmatic example is

a space vehicle landing on the surface of the Moon or Mars and releasing a robotic rover for exploring nearby the landing site. The rover can be equipped with a robotic manipulator for delivering instruments to the surface.

Space robotics is a challenging endeavor with one of the highest ratios of cost per mission over rate of success, among science and engineering fields. Primary difficulties in the design and operation of space robotic systems include mass, volume and power limitations, reduced gravity (which affects many phenomena, including mechanical, thermal, fluidic, and biological ones), harsh environments with extreme temperature fluctuations, radiation, remoteness of operation, need of radio communication with a ground station over either a direct path or relayed by other spacecraft, and presence of a delay in communication due to distance (e.g., quantifiable as a fraction of a second around the Earth, a few seconds at the Moon, and a few minutes at Mars). Additional difficulties for planetary robotics include a priori unknown or uncertain terrain characteristics and the need to avoid cross-planetary contamination.

Space robotics is an essential aspect of many of the current and future space exploration and utilization missions, and it will play an increasingly important role as technological progress continues in computing, control, space systems engineering, and robotic autonomy. For a historical perspective on space robotics, also see Gao and Chien (2017).

Fundamentals

This section introduces the basic functional principles, technologies, and engineering practices that are utilized in space robotics.

A spacecraft is a self-contained vehicle system designed to operate in space. It uses electrical energy, commonly produced by onboard solar panels and stored in batteries, to power its components. The main subsystems of a spacecraft include structure, electrical, computing, communication, thermal control, sensors and actuators, propulsion, payload instruments, mechanisms,

and software. A spacecraft is launched into space from the surface of the Earth as a payload of a multistage rocket launch vehicle or launcher. After orbit insertion the spacecraft is separated from the launcher and is in a natural (i.e., when control actions are off) dynamic state of free falling and free tumbling, in a quasi-vacuum environment. The center of mass of a spacecraft moves along an orbit, which – in most cases – can be modeled as either a circle or an ellipse with the center of the attracting body (e.g., the Earth) at one of its foci. Minute environmental actions (forces and torques) on an orbiting spacecraft typically have a negligible effect over a short time (relative to a conventionally defined “time constant” of the system, such as the orbital period) but a substantial effect over a longer time. The most important environmental actions might include residual aerodynamic forces and torques; solar pressure forces and torques; magnetic torques; and gravity gradient forces and torques.

After orbit insertion, a spacecraft is maneuvered by control actions in order to reach and maintain the orbit and orientation needed to fulfill its mission. The most common actuators to maneuver a spacecraft along its orbit, i.e., to generate an external force that changes its orbital velocity, are jet thrusters. A jet thruster works on the basis of the conservation of linear momentum. It generates a force on the spacecraft by expelling propellant in the opposite direction. The most common actuators to reorient a spacecraft, i.e., to generate a torque that changes its angular velocity and orientation, are again jet thrusters but also magnetic actuators and momentum-exchange devices.

Sensors commonly used for space robotic systems include onboard attitude navigation sensors, such as Sun sensors, star sensors, magnetometers, and rate gyroscopes; onboard orbital navigation sensors, such as optical sensors, Global Position System (GPS) receivers (for some of the orbits around Earth), and celestial navigation sensors; Earth-based navigation sensors, such as radar and electromagnetic range and velocity sensors; onboard configuration sensors, such as displacement sensors at the joints of robotic manipulators; and onboard relative navigation sensors like

artificial vision systems and radar for determining the relative position and velocity of a co-orbiting target object.

An interplanetary spacecraft usually requires considerably more complicated orbital maneuvers than a spacecraft orbiting around the Earth. In fact, an interplanetary flight involves orbiting different central bodies in sequence, including, for instance, Earth, Sun, and Mars. For planetary space robotic systems, those maneuvers include also a descent and landing on the target body.

Unmanned space robotic systems can be either tele-operated or tele-commanded from a ground station: in the latter case, a sequence of operations is commanded for later execution. Furthermore, unmanned spacecraft can rely – at least partially – on autonomous onboard command and operation scheduling and execution. Autonomous execution and command capability become necessary when the tasks are either of a repetitive nature or impossible to be commanded and executed remotely, because of a communication unreachability or a communication delay that is long with respect to the duration of the task itself. Finally, manned space robotic systems can also be operated by onboard crew members.

Core Disciplines

The core disciplines of space robotics are listed below together with selected references to specialized literature.

Engineering Mechanics: is the science concerned with the study of the physical behavior of material bodies, with interest generally focused on the mathematical description of their configuration and motion. Engineering mechanics is rooted in Newtonian classical physics and mathematical analysis and encompasses the two subtopics of kinematics (position, orientation, and their evolutions in time) and dynamics (effect of forces and torques). Among the many bibliographic references on this subject, Likins (1973) gives a rigorous and complete introduction from the astronautical engineering perspective. Stemming from engineering mechanics are the subjects of multibody

mechanics and mechanisms that are concerned with the modeling of systems consisting of multiple interconnected parts which can move relatively to each other. See, for instance, Wittenburg (2007) and Conley (1998).

Space Flight Mechanics (a.k.a. Astrodynamics or Astronautics): is the science concerned with the study of modeling, designing, and directing the translational and rotational trajectories of space vehicles, including rocket launchers, orbiting artificial satellites, and reentry vehicles. Comprehensive textbooks are here listed from the most introductory to the most advanced: Bate et al. (1971), Vallado and McClain (2013), Walter (2012), Schaub and Junkins (2018), Hughes (2012), and Gurfil and Seidelmann (2016).

Robotics: is the science concerned with the study of systems that can replace human beings in the execution of physical tasks. It is rooted in multibody mechanics and control system engineering. Primary topics include the kinematic, dynamic, motion planning, navigation, and control of robotic systems. Most commonly studied robotic systems are fixed-base robotic manipulators and wheeled rovers. Excellent references on general robotics include Siciliano et al. (2010) and Siciliano and Khatib (2008).

Guidance, Navigation, and Control: guidance is concerned with determining a reference trajectory for the evolution in time of the state of a physical system (i.e., of the configuration and its rate of change). Navigation is concerned with estimating the current state of the system. Finally, control is concerned with using the method of “feedback” in order to command the actuators to act on the system to follow the desired reference trajectory while rejecting disturbances due to un-modeled dynamic effects, uncertainties, and disturbances. Textbooks on these subjects include Kirk (2012) and Wie (2015). Also see the articles by Crassidis and Zanetti and D’Sousa in this book.

Space System Engineering: is concerned with the analysis, design, integration, and testing of spacecraft and their missions. Space System Engineering involves the concurrent and iterative design of all of the subsystems into an integrated spacecraft system. The design of a spacecraft

aims essentially at satisfying specific mission goals while minimizing the overall cost, mass, and volume, the last two factors being upper-bounded by launch constraints. Furthermore, system reliability needs to be maximized. In fact, spacecraft are typically unreachable and unserviceable during their operations. The mentioned factors in spacecraft design result in a general conservative approach and in the use of well-proven technologies that often lag years behind the latest commercially available technologies used in other fields. Standard references include in the area of Space System Engineering Wertz et al. (2011) and Fortescue et al. (2003).

Mathematical Model of an Orbiting Space Robot

This section introduces – for the sake of offering a high-level physical insight – the equations of motion that are used to model a typical space robotic system.

Let us consider the example of a space robotic system consisting of an Earth-orbiting spacecraft equipped with a robotic manipulator. The robotic manipulator consists of a series of rotational joints and rigid links, terminating with an end effector. A formally straightforward extension of the analysis is possible for more complicated systems, including multiple manipulators. Details on the subject are reported, for instance, in Xu and Kanade (1992) and Wilde et al. (2018).

The governing equations of motion of the spacecraft-manipulator system can be written – in compact form – as follows:

$$\mathbf{H}\dot{\mathbf{u}} + \mathbf{C}\mathbf{u} = \boldsymbol{\tau}, \quad (1)$$

where $\mathbf{H} \in \mathcal{R}^{(n+6) \times (n+6)}$ is the *Generalized Inertia Matrix*, which is positive definite and symmetric, n is the number of links of the manipulator (while the base spacecraft is conventionally indicated by the index 0, each successive joint and link of the manipulator are indicated by indexes from 1 to n), $\mathbf{C} \in \mathcal{R}^{(n+6) \times (n+6)}$ is the *Convective Inertia Matrix*, $\mathbf{u} \in \mathcal{R}^{(n+6)}$ is the

Generalized Velocity Matrix, and $\boldsymbol{\tau} \in \mathcal{R}^{(n+6)}$ is the *Generalized Force Matrix*.

The Generalized Inertia Matrix depends on the system geometry, i.e., on the mass and inertia tensor of each of the bodies composing the space robot, and on its current configuration, i.e., on the absolute orientation and position of the base and the relative angular displacement of each of the manipulator links. The Generalized Velocity Matrix contains the angular velocity and linear velocity of the base spacecraft, each having three scalar components on a chosen reference Cartesian coordinate system (e.g., fixed with respect to the inertial frame) and the n relative rotational speeds of the manipulator joints. Furthermore, the Convective Inertia Matrix depends on the system geometry, on the system current configuration, and on its current velocities (elements of the Generalized Velocity Matrix). Finally, the Generalized Force Matrix contains all of the external and internal forces and torques acting on the system, including base-spacecraft actuation forces and torques, manipulator joint torques, forces and torques due to the interaction with another orbiting body, and orbital disturbance force and torques.

Given specific space robotic systems, the above equations of motions are equivalently derived by using either the Lagrangian approach or the Newton-Euler approach. While the former starts with the expression of the kinetic and potential energy of the whole system and then apply the Lagrangian equations formality, the latter builds up the equation of motion by successively taking into account each of the rigid bodies composing the system and applying the Newton's second law of translation and the Euler's law of rotation. The Newton-Euler approach is often preferred in literature because of its iterative nature which offers more scalability up to systems with many degrees of freedom.

In order to better illustrate the mechanics of motion of a spacecraft-manipulator system and, in particular, the occurring dynamic coupling between the base spacecraft and the manipulator, it is useful to rewrite Eq.(1) in the following form:

$$\begin{bmatrix} \mathbf{H}_0 & \mathbf{H}_{0m} \\ \mathbf{H}_{0m}^T & \mathbf{H}_m \end{bmatrix} \begin{bmatrix} \dot{\mathbf{u}}_0 \\ \dot{\mathbf{u}}_m \end{bmatrix} + \begin{bmatrix} \mathbf{C}_0 & \mathbf{C}_{0m} \\ \mathbf{C}_{m0} & \mathbf{C}_m \end{bmatrix} \begin{bmatrix} \mathbf{u}_0 \\ \mathbf{u}_m \end{bmatrix} = \begin{bmatrix} \boldsymbol{\tau}_0 \\ \boldsymbol{\tau}_m \end{bmatrix}, \quad (2)$$

where $\mathbf{H}_0$ is the 6×6 inertia matrix of the base spacecraft, $\mathbf{H}_m$ is the $n \times n$ inertia matrix of the robotic manipulator, and $\mathbf{H}_{0m}$ is the $6 \times n$ dynamic-coupling inertia matrix that expresses the contribution of the dynamic coupling between the manipulator and the base spacecraft to the kinetic energy of the spacecraft-manipulator system. Analogously, for the sub-matrices of the Convective Inertia Matrix $\mathbf{C}_0$, $\mathbf{C}_m$, $\mathbf{C}_{0m}$, and $\mathbf{C}_{m0}$. Furthermore, $\mathbf{u}_0$ contains the six generalized velocities of the base spacecraft, and $\mathbf{u}_m$ contains the n generalized velocities pertaining to the robotic manipulator. Finally, $\boldsymbol{\tau}_0$ contains the six generalized forces on the base spacecraft, and $\boldsymbol{\tau}_m$ contains the n generalized forces at the manipulator joints.

As it is clear from Eq. (2), the motion of the spacecraft base and the robotic manipulator are dynamically coupled. Notably, the coupling effect becomes more important as the ratios between mass and inertia of the manipulator vs mass and inertia of the base increase. At the limit when the mass and inertia of the base are infinitely larger than the mass and inertias of the manipulator, Eq. (2) becomes equivalent to the equations of motion of a fixed-base robotic manipulator.

The above equations of motion of a spacecraft-manipulator system can be used to solve either the *forward dynamics* problem of mapping a history of generalized forces onto the resulting history of motion in terms of base-spacecraft and manipulator motion or the *inverse dynamics* problem of mapping a desired history of motion onto the needed history of generalized forces to generate that motion. Furthermore, the equations of motion can be used to design and simulate the effect of guidance and control methods.

The most common maneuver strategies for a spacecraft-manipulator system are *free-floating* and *free-flying* maneuvers. The former refers to a maneuver during which the base spacecraft is

not controlled by thrusters while the manipulator motion is controlled through the actions at its joints, while the latter refers to a maneuver during which the spacecraft is controlled by thrusters during the manipulator motion. Other type of maneuvers are possible: see Wilde et al. (2018) for more details. In particular, the *free-floating* approach is preferred, whenever the related constrained work-space size is acceptable for the task at hand. In fact, the *free-floating* approach elegantly enables a propellant-less maneuvering by exploiting the dynamic coupling between the base spacecraft and the onboard robotic manipulator.

By assuming that the spacecraft-manipulator system is not subjected to external forces or torques, and by integrating in time the first six equations of Eq. (2), related to the base-link, yields

$$\mathbf{H}_0 \mathbf{u}_0 + \mathbf{H}_{0m} \mathbf{u}_m = \begin{bmatrix} \mathcal{L} \\ \mathcal{P} \end{bmatrix}, \quad (3)$$

with $\mathcal{P}$ denoting the three components of the total absolute linear momentum and $\mathcal{L}$ the three components of the total absolute angular momentum. Both of these quantities are conserved, based on the stated hypotheses. These momenta equations constrain the motion of the spacecraft-manipulator system as an under-actuated system in a nonholonomic fashion. They enable to design *free-floating* maneuvers and to compute the reaction forces between the manipulator and the base spacecraft. See Xu and Kanade (1992) for more details.

Current Efforts and Perspective on Future Developments

Space robotics is listed among the key technologies and aerospace developmental priorities for the decades to come in both the 2015 NASA Technology Roadmap (Miller 2015) and in the recently published 2020 NASA Technology Taxonomy (Terrier 2020).

Notably, space robotics is one of the enabling technologies for the following missions that are considered with high priority worldwide:

On-orbit Servicing, Assembly, and Manufacturing (OSAM). This definition refers to the use

of spacecraft equipped with robotic manipulators or other robotic mechanisms for conducting servicing operations such as inspection, refueling, or maintenance of orbiting satellites; to assemble large structures in space made from smaller constituent modules, such are needed for future space stations, space telescopes, and possibly space solar power generators; to manufacture structure in space, e.g., via 3D printing; or to manufacture engineering or biological items for later use on Earth. Examples of recently flown missions of this kind include the Northrop Grumman's Mission Extension Vehicle (2019) and the NASA Seeker CubeSat (2019). Planned missions include the Defense Advanced Research Projects Agency (DARPA) Robotic Servicing of Geosynchronous Satellites (RSGS), the NASA Restore-L, the Effective Space Solutions' Space Drone, and the Made in Space's Archinaut One.

Space Debris Removal. This refers to the use of spacecraft-manipulator systems for grappling and deorbiting large space debris. A planned mission of this kind is the European Space Agency (ESA) e-Deorbit.

Solar System Exploration and in Situ Utilization. Space robotics will continue to play an essential role in the exploration and

utilization of orbital space and of the solar system's bodies, supporting both unmanned and manned missions (also see Roesler 2019). Examples of recently flown missions of this kind include the Japan Aerospace Exploration Agency (JAXA) Hayabusa-2 spacecraft that performed subsurface sample-gathering touchdown in 2019 on the asteroid Ryugu and the China National Space Administration (CNSA) Chang'e 4, first Spacecraft Lander and Rover deployed on the far side of the Moon (2019), the NASA OSIRIS-REx, launched in 2018 and planned to collect and return a sample from Asteroid Bennu in 2020. Planned missions of this kind include the ESA European Robotic Arm (ERA) to be attached to the Russian segment of the International Space Station, the ESA ExoMars Mars Rover mission, the CNSA Chang'e 5 lunar sample return mission, the NASA Mars 2020 Mars rover mission, the NASA VIPER lunar rover planned to explore permanently shadowed areas in the lunar south pole region, and the NASA Gateway equipped with the Canadarm 3 robotic arm. Also see Figs. 1, 2, and 3.

Space Defense. During the last decade, space has risen to become a contested environment and space defense a key component of the Great

Space Robotics, Fig. 1

Kibo laboratory of the International Space Station in July 2019. (Picture Credit: NASA–National Aeronautics and Space Administration).

Power Competition involving China, Russia, and the United States. This is reflected in the establishment of the US Space Force in December 2019. It is foreseeable that space robotics

technology could play a critical role in both defensive and offensive military capabilities in space. However, it is the author's hope that international policy and diplomacy, under the auspices

of the United Nations Office of Outer Space Affairs (UNOOSA), will be able to avoid an escalation of conflict in space and to contribute to set the main focus of space engineering and science toward peaceful uses for mankind's benefit.

Important areas of active research aiming at meeting the future needs and challenges of space robotics include autonomous rendezvous, proximity operations, docking, and capture; hardware and algorithms for improved sensing and perception; high-level autonomy and failure management and robustness; human-robot interaction; Guidance, Navigation and Control; manipulation and mobility; modeling, simulation, and on-the-ground experimentation (also see Wilde et al. 2019); modularity; standardization of technology and practices, as fostered – for instance – by the Consortium for Execution of Rendezvous and Servicing Operations (CONFERS); system engineering methods; legal aspects; and national and international policy.

Dedication

The author would like to dedicate this article to the memory of astronaut-select Prof. Franco Rossitto, space flight passionate, mentor, and friend.

Spacecraft Attitude Determination

John L. Crassidis

Department of Mechanical and Aerospace Engineering, University at Buffalo, The State University of New York, Buffalo, NY, USA

Abstract

Spacecraft attitude determination refers to process of determining the orientation of a vehicle in orbit from onboard attitude sensor

measurements. Knowledge of the attitude is crucial to point a spacecraft to a desired orientation using an attitude control system. The sensor measurements are usually put into vector form, as well as their associated reference vectors. If all the measured and reference vectors are error-free, then the rotation (attitude) matrix is the same for all sets of observations. However, if measurement errors exist, such as noise, then a least-squares type method must be used. Filtering algorithms are typically used to filter noisy measurements, and estimate other quantities such as calibration parameters. This chapter provides an overview of attitude determination and filtering for the purpose of attitude determination of spacecraft in orbit.

Keywords

Wahba's problem · q Method ·
Multiplicative extended Kalman filter

Introduction

Most spacecraft have pointing requirements in order to meet their mission objectives. For example, the Geostationary Operational Environment Satellite (GOES) series, which supply the weather pictures seen on televised weather programs, are required to point their onboard weather sensing devices at the Earth to within a high accuracy in order to obtain detailed images. Other applications are not as straightforward as GOES. For example, the pointing requirements for the International Space Station (ISS) are typically defined to mitigate the effects of external torque disturbances, such as gravity gradient torques and atmospheric drag torques, so that actuator usage can be minimized. All spacecraft have both *knowledge* and *control* requirements that makeup the overall pointing requirements. For example, for the ISS the knowledge requirement is 0.5 degrees per axis (3σ), and the control requirement maintains the attitude ± 5 degrees per axis. Obviously, the control requirement cannot be larger than

the knowledge requirement. The purpose of this chapter is to introduce the basics of spacecraft attitude determination, which is used to fulfill spacecraft knowledge requirements.

When one uses the term “attitude” to describe the orientation of a spacecraft, one must first describe the frames required to provide the proper context behind the meaning of the attitude. The attitude of a spacecraft is defined as its orientation with respect to some reference frame. If the reference frame is non-moving, then it is commonly referred to as an *inertial* frame. To describe the attitude, two coordinate systems are usually defined: one on the spacecraft body and one on the reference frame. For most dynamical applications, these coordinate systems have orthogonal unit vectors that follow the right-hand rule. The *attitude matrix* (A), often referred to as the direction cosine matrix or rotation matrix, maps one frame to another (for spacecraft kinematics this mapping is usually from the reference frame to the vehicle body frame). A geometrical representation of this concept is shown in Fig. 1, where the r_i ($i = x, y, z$) quantities correspond to the inertial frame and the b_i quantities correspond to the spacecraft body frame.

There are two types of spacecraft attitude determination. One uses any number of measurement observations at a specified time point without other information (such as motion models) to determine the attitude. This type requires at least two non-collinear vectors to determine a solution. Many algorithms are available to solve this type of problem; see Markley and Mortari (2000) for a review of several algorithms. The other type incorporates the measurements with kinematic, or possibly dynamic, models of motion to provide a “filtered” attitude solution. In general, filtered processes provide better accuracy than the first form of spacecraft attitude determination. Many algorithms are available to solve this type of problem as well; see Crassidis et al. (2007) for a survey of several algorithms.

Body frame observations can be obtained from various attitude sensors. Star sensors are used to provide line-of-sight (LOS) vectors to pre-identified stars. These are generally the most accurate attitude sensors, which can provide ≈ 1

Spacecraft Attitude Determination, Fig. 1

Relationship between reference and body frames

arc seconds off boresight and ≈ 100 arc seconds around the boresight information. Also, modern-day star sensors can track multiple stars, thus providing a mechanism to determine an attitude without other sensors. Sun sensors essentially provide the same LOS information as star sensors, but are not as accurate. Earth-horizon sensors provide a direction to the geocenter with accuracies from 0.1° in near-Earth orbit to 0.03° in geostationary orbit using a fixed-head sensor. Three-axis magnetometers measure the three components of the magnetic field, but only two degrees of freedom are actually provided. Obtainable accuracies depend more on the errors in the magnetic field model than on sensor noise in the magnetometer; typical accuracies range from 0.5° to 3° . Sun sensors, Earth-horizon sensors, and three-axis magnetometers cannot be used alone to determine the attitude completely; however, these sensors are often used simultaneously to determine the attitude of a spacecraft. Another attitude sensor relies on signals obtained from the Global Positioning System (GPS). This sensor measures carrier differences using multiple antennae to determine angles to various GPS satellites, which can be used to completely determine the attitude, to about a few degrees, if enough angles are given. Gyros are used to propagate a kinematics model, which, if an accurate initial attitude estimate is given, provide an attitude estimate without external sensors. How-

Spacecraft Attitude Determination, Table 1 Typical attitude sensor performance ranges

Sensor	Typical performance range
Star sensors	0.0003° to 0.01°
Sun sensors	0.005° to 3°
Horizon sensors	0.1° to 1° (Scanner/Pipper) $<0.1^\circ$ to 0.25° (Fixed head)
Magnetometers	0.5° to 3°
GPS	0.5° to 3°
Gyros	0.003 to 1 deg/h

ever, all gyros inherently drift over time, which degrades the attitude accuracy. A summary of the typical sensor performance ranges is shown in Table 1.

Attitude Determination

This section provides a review of the fundamentals of attitude determination. First, the mathematics of the underlying observation equations are summarized. Then, the popular q method is shown, which solves Wahba's classic problem. Finally, maximum likelihood estimation is shown.

Attitude sensors are generally modeled using the following (noiseless) observation model:

$$\mathbf{b} = \mathbf{A} \mathbf{r} \tag{1}$$

where A is the 3×3 attitude matrix, $\mathbf{r}$ is a 3×1 assumed-known *reference vector* of length one, and $\mathbf{b}$ is a 3×1 *body-observation vector*, also of length one. For attitude determination, right-handed orthogonal coordinates frames are always assumed. The attitude matrix maps coordinates in the reference frame to coordinates in the body frame. The body coordinate frame is usually defined through the initial vehicle design procedure. Many reference coordinate frames can be employed, which are usually dictated by the mission objectives. For example, if a stellar pointing requirement is given, then an inertially fixed frame is often used, where the motion of the stars is zero with respect to this frame. The star locations with respect to this frame are stored in a star catalogue.

The parameterization of choice for attitude determination is the quaternion, defined by $\mathbf{q} \equiv [q_1 \ q_2 \ q_3 \ q_4]^T = [q_1 \ q_2 \ q_3 \ q_4]^T$. The corresponding attitude matrix in Eq. (1) using the quaternion description of the attitude is given by $A(\mathbf{q}) = \mathcal{E}^T(\mathbf{q})\Psi(\mathbf{q})$, with

$$\mathcal{E}(\mathbf{q}) \equiv \begin{bmatrix} q_4 I_{3 \times 3} + [\mathbf{q}_{1:3} \times] \\ -\mathbf{q}_{1:3}^T \end{bmatrix} = \begin{bmatrix} q_4 & -q_3 & q_2 \\ q_3 & q_4 & -q_1 \\ -q_2 & q_1 & q_4 \\ -q_1 & -q_2 & -q_3 \end{bmatrix} \quad (2a)$$

$$\Psi(\mathbf{q}) \equiv \begin{bmatrix} q_4 I_{3 \times 3} - [\mathbf{q}_{1:3} \times] \\ -\mathbf{q}_{1:3}^T \end{bmatrix} = \begin{bmatrix} q_4 & q_3 & -q_2 \\ -q_3 & q_4 & q_1 \\ q_2 & -q_1 & q_4 \\ -q_1 & -q_2 & -q_3 \end{bmatrix} \quad (2b)$$

where $I_{3 \times 3}$ is a 3×3 identity matrix and $[\mathbf{q}_{1:3} \times]$ is the standard “cross product matrix” Markley and Crassidis (2014). Successive rotations can be accomplished using quaternion multiplication: $A(\mathbf{q}')A(\mathbf{q}) = A(\mathbf{q}' \otimes \mathbf{q})$. The composition of the quaternions is bilinear, with

$$\mathbf{q}' \otimes \mathbf{q} = [\Psi(\mathbf{q}') : \mathbf{q}'] \mathbf{q} = [\mathcal{E}(\mathbf{q}) : \mathbf{q}] \mathbf{q}' \quad (3)$$

Note that here we adopt the convention of Lefferts et al. (1982) who multiply the quaternions in the same order as the attitude matrix

multiplication. Also, the inverse quaternion is defined by $\mathbf{q}^{-1} \equiv [-\mathbf{q}_{1:3}^T \ q_4]^T$. Since a four-dimensional vector is used to describe three dimensions, the quaternion components cannot be independent of each other. The quaternion satisfies a single constraint given by $\mathbf{q}^T \mathbf{q} = 1$.

There is no such thing as a “perfect measurement,” because every sensor contains errors, either in the form of random noise or systematic (nonrandom) errors. Oftentimes, systematic errors are reduced through pre-mission calibration procedures, although sensors may still require on-orbit calibration due to environmental effects or other sources of errors, such as aging of components. Standard attitude determination approaches assume that the systematic errors are zero, or negligible, and model the body measurements as

$$\tilde{\mathbf{b}} = A \mathbf{r} + \mathbf{v} \quad (4)$$

where $\mathbf{v}$ is a zero-mean Gaussian noise vector with assumed known covariance. For unit vector observations, the problem is even more complicated because a unit vector is never “observed.” For example, the body measurement from a star tracker is modeled by

$$\tilde{\mathbf{b}} \equiv \frac{1}{\sqrt{f^2 + (x + v_x)^2 + (y + v_y)^2}} \begin{bmatrix} -(x + v_x) \\ -(y + v_y) \\ f \end{bmatrix} \quad (5)$$

where f is the known focal length, x and y are the true focal plane observations, and v_x and v_y are zero-mean Gaussian noise processes with the same variance, σ^2 . The desired unit vector measurement model is given by Eq. (4). Clearly, using the measurement model in Eq. (5) does not produce a Gaussian process for $\mathbf{v}$, even though v_x and v_y are Gaussian. Fortunately, Shuster and Oh (1981) have shown that nearly all the probability of the errors is concentrated on a very small area about the direction of $A \mathbf{r}$, so the sphere containing that point can be approximated by a tangent plane, characterized by $\mathbf{v}^T A \mathbf{r} = 0$,

$E\{\mathbf{v}\} = \mathbf{0}$, and

$$E\{\mathbf{v}\mathbf{v}^T\} = \sigma^2 [I_{3 \times 3} - (A\mathbf{r})(A\mathbf{r})^T] \quad (6) \quad \text{with}$$

where $E\{\}$ denotes expectation. Note that this matrix is always singular. For large signal-to-noise ratios, which is valid for most spacecraft attitude sensors, the noise vector $\mathbf{v}$ is approximately Gaussian with covariance given by Eq.(6). This is highly important because Gaussian assumptions tend to greatly simplify the mathematical formulations used to develop the attitude determination algorithms.

Wahba's Problem

In 1965 Grace Wahba (1965) posed a problem that involves finding the proper orthogonal matrix A that minimizes the loss function

$$J(A) = \frac{1}{2} \sum_{i=1}^N a_i \|\tilde{\mathbf{b}}_i - A\mathbf{r}_i\|^2, \quad \text{subject to } A^T A = I_{3 \times 3} \quad (7)$$

where a_i are nonnegative weights and N is the total number of measurements. The loss function can be rewritten as $J(A) = \lambda_0 - \text{trace}(A B^T)$, where trace is the matrix trace operator and $\lambda_0 \equiv \sum_{i=1}^N a_i$. The matrix B is defined by

$$B \equiv \sum_{i=1}^N a_i \tilde{\mathbf{b}}_i \mathbf{r}_i^T = \begin{bmatrix} B_{11} & B_{12} & B_{13} \\ B_{21} & B_{22} & B_{23} \\ B_{31} & B_{32} & B_{33} \end{bmatrix} \quad (8)$$

Clearly, $J(A)$ is minimized when $\text{trace}(A B^T)$ is maximized.

At first glance, the solution to this problem seems to follow a standard least-squares approach. However, the constraint $A^T A = I_{3 \times 3}$ makes the problem more difficult. Since the time this problem was first posed, many solutions have been proposed. A useful solution was given by Davenport who parameterized the attitude by a unit quaternion Markley and Crassidis (2014). Parameterizing the attitude matrix using a quaternion leads to maximizing

$$J'(\mathbf{q}) = \mathbf{q}^T K \mathbf{q}, \quad \text{subject to } \mathbf{q}^T \mathbf{q} = 1 \quad (9)$$

$$K \equiv \begin{bmatrix} S - \text{trace}(B) I_{3 \times 3} & \mathbf{z} \\ \mathbf{z}^T & \text{trace}(B) \end{bmatrix} \quad (10)$$

where $S \equiv B + B^T$ and $\mathbf{z} \equiv [B_{23} - B_{32} \ B_{31} - B_{13} \ B_{12} - B_{21}]^T = \sum_{i=1}^N a_i \tilde{\mathbf{b}}_i \times \mathbf{r}_i$. The optimal quaternion solution, denoted by $\hat{\mathbf{q}}$, is given by computing the normalized eigenvector of K with the largest eigenvalue, with

$$K \hat{\mathbf{q}} = \lambda_{\max} \hat{\mathbf{q}} \quad (11)$$

where $\lambda_{\max}$ is the maximum eigenvalue and $\hat{\mathbf{q}}$ is its corresponding unit eigenvector, which is also the optimal estimate of the quaternion.

Although Davenport's solution is useful, it was not practical for spacecraft applications in the 1970s and early 1980s because the eigenvector decomposition was too computationally burdensome. The problem was overcome by Shuster's QUaternion ESTimator (QUEST) algorithm Shuster and Oh (1981), which was first applied to the Magnetic Field Satellite mission in 1979, and to date has been the most widely used attitude determination algorithm.

Maximum Likelihood Estimation

Shuster noted that choosing the weights to be inverse variances, $a_i = \sigma_i^{-2}$ makes Wahba's problem a maximum likelihood estimation problem Shuster (1989). The "Fisher information matrix" (FIM) for a parameter vector $\mathbf{x}$ is given by

$$F = E \left\{ \frac{\partial}{\partial \mathbf{x} \partial \mathbf{x}^T} J(\mathbf{x}) \right\} \quad (12)$$

where $J(\mathbf{x})$ is the negative log-likelihood function, which is the loss function in this case (neglecting terms independent of A). Asymptotically, the FIM tends to the inverse of the estimate error covariance, denoted by P . This matrix is useful because it can be used to develop 3σ bounds between the true attitude and the estimated attitude. The FIM for the attitude is expressed in terms of incremental error angles,

$\delta\boldsymbol{\vartheta}$, defined according to

$$A \hat{A}^T = e^{-[\delta\boldsymbol{\vartheta} \times]} \approx (I_{3 \times 3} - [\delta\boldsymbol{\vartheta} \times]) \quad (13)$$

where A is treated as the *true* attitude here and $\hat{A}$ is its *estimate*. The parameter vector is now given by $\mathbf{x} = \delta\boldsymbol{\vartheta}$, and the error covariance is defined by $P = E\{\mathbf{x}\mathbf{x}^T\} - E\{\mathbf{x}\}E^T\{\mathbf{x}\}$, which is given by Shuster (1989)

$$P = \left(-\sum_{i=1}^N \sigma_i^{-2} [A \mathbf{r}_i \times]^2 \right)^{-1} \quad (14)$$

The attitude A is evaluated at its respective *true* value. In practice, though, $A \mathbf{r}_i$ is often replaced with the measurement $\hat{\mathbf{b}}_i$, which allows a calculation of the error covariance without computing an attitude.

Attitude Filtering

The workhorse of attitude filtering is the extended Kalman filter (EKF) Crassidis and Junkins (2012). The EKF uses a continuous-time model with discrete-time measurements to provide optimal state estimates. The state estimate model is propagated forward in time until a measurement occurs, given at time t_1 . Then a discrete-time state update occurs, which updates the final value of the propagated state $\hat{\mathbf{x}}_1^-$ to the new state $\hat{\mathbf{x}}_1^+$. Finally, this state is then used as the initial condition to propagate the state estimate model to time t_2 . The scheme continues forward in time, updating the state when a measurement occurs.

The continuous-time gyro sensors are typically modeled as

$$\tilde{\boldsymbol{\omega}} = \boldsymbol{\omega} + \boldsymbol{\beta} + \boldsymbol{\eta}_v \quad (15a)$$

$$\dot{\boldsymbol{\beta}} = \boldsymbol{\eta}_u \quad (15b)$$

where $\tilde{\boldsymbol{\omega}}$ is the measured rate, $\boldsymbol{\omega}$ is the true rate, $\boldsymbol{\beta}$ is the drift, and $\boldsymbol{\eta}_v$ and $\boldsymbol{\eta}_u$ are independent zero-mean Gaussian white-noise processes with

$$E\{\boldsymbol{\eta}_v(t)\boldsymbol{\eta}_v^T(\tau)\} = \sigma_v^2 \delta(t - \tau) I_{3 \times 3} \quad (16a)$$

$$E\{\boldsymbol{\eta}_u(t)\boldsymbol{\eta}_u^T(\tau)\} = \sigma_u^2 \delta(t - \tau) I_{3 \times 3} \quad (16b)$$

where $\delta(t - \tau)$ is the Dirac delta function. A more general gyro sensor model includes scale factors and misalignments, which can also be estimated in real time Markley and Crassidis (2014).

The EKF works on the premise of using a Taylor series expansion of the nonlinear model. Here the model contains the quaternion kinematics, as well as the drift in the gyro:

$$\dot{\mathbf{q}} = \frac{1}{2} \boldsymbol{\varepsilon}(\mathbf{q})(\tilde{\boldsymbol{\omega}} - \boldsymbol{\beta} - \boldsymbol{\eta}_v) \quad (17a)$$

$$\dot{\boldsymbol{\beta}} = \boldsymbol{\eta}_u \quad (17b)$$

Note that the gyro measurements are used in the kinematics model directly. Linearizing Eq. (17) using a straightforward Taylor series expansion has a number of problems. The most problematic issue is the fact that the quaternion normalization will be destroyed in the linearization. To overcome this problem, a “multiplicative EKF” (MEKF) Markley and Crassidis (2014) is used in the linearization process. The quaternion equivalent of Eq. (13) is given by

$$\delta\mathbf{q} = \mathbf{q} \otimes \hat{\mathbf{q}}^{-1} \approx \begin{bmatrix} 0.5 \delta\boldsymbol{\vartheta} \\ 1 \end{bmatrix} \quad (18)$$

The MEKF uses $\delta\boldsymbol{\vartheta}$ as the “local parameterization,” while the quaternion is used as the “global parameterization.” This allows the state vector to be reduced by one state. The six-state MEKF attitude filter is shown in Table 2, where $F(t)$, $G(t)$, and $Q(t)$ are given by

$$\begin{aligned} F(t) &= \begin{bmatrix} -[\hat{\boldsymbol{\omega}}(t) \times] & -I_{3 \times 3} \\ 0_{3 \times 3} & 0_{3 \times 3} \end{bmatrix}, \\ G(t) &= \begin{bmatrix} -I_{3 \times 3} & 0_{3 \times 3} \\ 0_{3 \times 3} & I_{3 \times 3} \end{bmatrix}, \\ Q(t) &= \begin{bmatrix} \sigma_v^2 I_{3 \times 3} & 0_{3 \times 3} \\ 0_{3 \times 3} & \sigma_u^2 I_{3 \times 3} \end{bmatrix} \end{aligned} \quad (19)$$

Spacecraft Attitude Determination, Table 2
MEKF for attitude filtering

Initialize	$\hat{\mathbf{q}}(t_0) = \hat{\mathbf{q}}_0, \quad \hat{\boldsymbol{\beta}}(t_0) = \hat{\boldsymbol{\beta}}_0$ $P(t_0) = P_0$
Gain	$K_k = P_k^- H_k^T (\hat{\mathbf{x}}_k^-) [H_k (\hat{\mathbf{x}}_k^-) P_k^- H_k^T (\hat{\mathbf{x}}_k^-) + R_k]^{-1}$ $H_k (\hat{\mathbf{x}}_k^-) = \begin{bmatrix} [A(\hat{\mathbf{q}}^-) \mathbf{r}_1 \times] & 0_{3 \times 3} \\ \vdots & \vdots \\ [A(\hat{\mathbf{q}}^-) \mathbf{r}_N \times] & 0_{3 \times 3} \end{bmatrix}_{I_k}$
Update	$P_k^+ = [I - K_k H_k (\hat{\mathbf{x}}_k^-)] P_k^-$ $\Delta \hat{\mathbf{x}}_k^+ = K_k [\tilde{\mathbf{y}}_k - \mathbf{h}_k (\hat{\mathbf{x}}_k^-)]$ $\Delta \hat{\mathbf{x}}_k^+ \equiv \begin{bmatrix} \delta \hat{\boldsymbol{\theta}}_k^{+T} & \Delta \hat{\boldsymbol{\beta}}_k^{+T} \end{bmatrix}^T$ $\mathbf{h}_k (\hat{\mathbf{x}}_k^-) = \begin{bmatrix} A(\hat{\mathbf{q}}^-) \mathbf{r}_1 \\ A(\hat{\mathbf{q}}^-) \mathbf{r}_2 \\ \vdots \\ A(\hat{\mathbf{q}}^-) \mathbf{r}_N \end{bmatrix}_{I_k}$ $\hat{\mathbf{q}}^* = \hat{\mathbf{q}}_k^- + \frac{1}{2} \Xi (\hat{\mathbf{q}}_k^-) \delta \hat{\boldsymbol{\theta}}_k^+$ $\hat{\mathbf{q}}_k^+ = \hat{\mathbf{q}}^* / \ \hat{\mathbf{q}}^*\ $ $\hat{\boldsymbol{\beta}}_k^+ = \hat{\boldsymbol{\beta}}_k^- + \Delta \hat{\boldsymbol{\beta}}_k^+$
Propagation	$\hat{\boldsymbol{\omega}}(t) = \tilde{\boldsymbol{\omega}}(t) - \hat{\boldsymbol{\beta}}(t)$ $\dot{\hat{\mathbf{q}}}(t) = \frac{1}{2} \Xi (\hat{\mathbf{q}}(t)) \hat{\boldsymbol{\omega}}(t)$ $\dot{P}(t) = F(t) P(t) + P(t) F^T(t) + G(t) Q(t) G^T(t)$

where $0_{3 \times 3}$ is a 3×3 matrix of zeroes. The vector $\tilde{\mathbf{y}}$ is made up of the body measurements, and R_k is a block diagonal matrix with blocks given by $\sigma_i^2 I_{3 \times 3}$. Also, P denotes the error covariance from the filter now. Discrete-time propagation of the kinematics and error covariance is also possible Markley and Crassidis (2014).

Summary and Future Work

This chapter provided a fundamental algorithm, called the q method, to perform attitude determination from a collection of body and reference unit vectors. Any attitude determination algorithm requires at least two non-collinear vectors to determine a unique attitude. The error covariance derived from a maximum likelihood analysis is useful to quantify the expected errors between the true attitude and the estimated attitude. The most common attitude filter, called the multiplicative extended Kalman filter, was also introduced using vector observations along with

gyro measurements. This is a complementary filter in the sense that the gyros are used to filter the noisy measurements, while the measurements are used to calibrate the gyros in real time. For high-quality gyros, the filtered attitude solution is typically about an order of magnitude better than the one found from attitude determination algorithms. Future work should focus on deriving truly nonlinear filters that can guarantee stochastic stability from any initial condition. Other work entails deriving filters that are robust to possible non-Gaussian errors.

Spatial Description of Biochemical Networks

Pablo A. Iglesias

Electrical and Computer Engineering, The Johns Hopkins University, Baltimore, MD, USA

Abstract

Many biological behaviors require that biochemical species be distributed spatially throughout the cell or across a number of cells. To explain these situations accurately requires a spatial description of the underlying network. At the continuum level, this is usually done using reaction-diffusion equations. Here we demonstrate how this class of models arises. We also show how the framework is used in two popular models proposed to explain spatial patterns during development.

Keywords

Diffusion · Morphogen gradient · Pattern formation · Reaction-diffusion · Turing instability

Introduction

Cells are complex environments consisting of spatially segregated entities, including the nucleus and various other organelles. Even within these compartments, the concentrations of various biochemical species are not homogeneous, but can vary significantly. The proper localization of proteins and other biochemical species to their respective sites is important for proper cell function. This can be because the spatial distribution of signaling molecules itself confers information, such as when a cell needs to respond to a spatially graded cue to guide its motion (Iglesias and Devreotes 2008) or growth pattern (Lander 2013). Alternatively, information that is obtained in one part of the cell must be transmitted to another part of the cell, as when receptor-ligand binding at the cell surface leads to transcriptional responses in the nucleus. Frequently, describing the action of a biological network accurately requires not only that one account for the chemical interactions between the different components but that the spatial distribution of the signaling molecules also be considered.

Accounting for Spatial Distribution in Models

Mathematical models of biological networks usually assume that reactions take place in well-stirred vessels in which the concentrations of the interacting species are spatially homogeneous and hence need not be accounted for explicitly. These systems also assume that the volume is constant. When the spatial location of molecules in cells is important, the concentration of species changes in both time and space.

Compartmental Models

One way to account for spatial distribution of signaling components is through compartmental models. As the name suggests, in these models the cell is divided into different regions that are segregated by membranes. Within each compartment, the concentration of the network species

is assumed to be spatially homogeneous. The membranes in these models can be assumed to be either permeable or impermeable. In permeable membranes, information passes through small openings, such as ion channels or nuclear pores, which allow molecules to move from one side of the membrane to the other. With impermeable membranes, information must be transduced by transmembrane signaling elements, such as cell-surface receptors, that bind to a signaling molecule in one side of the membrane and release a secondary effector on the other side. Note that in this case, the membrane itself acts as a third compartment.

Compartmental models offer simplicity, since the reactions that happen in a single region obey the same reaction kinetics usually assumed in spatially homogeneous models. Even when the reactions involve more than one compartment, as in ligand-receptor binding, this can still be described by the usual reaction dynamics. Care must be taken, however, to account properly for the different effects on the respective concentrations as molecules move from one compartment to another. In models of spatially homogeneous systems, there is little practical difference between writing the ordinary-differential equations in terms of molecule numbers or concentrations, since the two are proportional to each other according to the volume, which is constant. In a compartmental model, if the molecule moves from one compartment to another, there is conservation of molecule numbers, but not concentrations. For example, if a species is found in two compartments with volumes V_1 and V_2 and transfer rates k_{12} and $k_{21} \text{ s}^{-1}$, then the differential equations describing transport between compartments can be expressed in terms of numbers (n_1 and n_2) as follows:

$$\begin{aligned}\frac{dn_1}{dt} &= -k_{12}n_1 + k_{21}n_2 \\ \frac{dn_2}{dt} &= +k_{12}n_1 - k_{21}n_2.\end{aligned}$$

Dividing by the respective volumes ($C_1 = n_1/V_1$ and $C_2 = n_2/V_2$), we obtain equations for the concentrations

$$\begin{aligned}\frac{dC_1}{dt} &= -k_{12}C_1 + k_{21}\left(\frac{V_2}{V_1}\right)C_2 \\ \frac{dC_2}{dt} &= +k_{12}\left(\frac{V_1}{V_2}\right)C_1 - k_{21}C_2.\end{aligned}$$

In the former case, the two equations add to zero, indicating that $n_1(t) + n_2(t) = \text{constant}$. In the latter, if $V_1 \neq V_2$, then $C_1(t) + C_2(t)$ varies over time as molecules move from one compartment to the other.

Diffusion and Advection

If the distribution of molecules inside any single compartment is spatially heterogeneous, then models must account for this spatial distribution. At the continuum level, this is done using reaction-diffusion equations. The basic assumption is a conservation principle expressed as a continuity equation:

$$\frac{\partial \rho}{\partial t} + \nabla j = f,$$

which relates the changes in the density (ρ) of a conserved quantity (in our case, the concentration of a species: $\rho = C$) to the flux j and any net production f . In biological networks, the latter represents the net effect of all the reactions that affect the concentration of the species including binding, unbinding, production, degradation, post-translational modifications, etc.

In biological models, the flux term usually comes from one of two sources: diffusion or advection. According to Fick's law, diffusive flux is proportional to the negative gradient of the concentration of the species as particles move from regions of high concentration to regions of low concentration. The coefficient of proportionality is the diffusion coefficient, D :

$$j_{\text{diff}} = -D\nabla C.$$

Fick's law describes thermally driven Brownian motion of molecules at the continuum level. If the species is embedded in a moving field, then the flux is proportional to the velocity of the underlying fluid. In this case, we have advective flow:

$$j_{\text{adv}} = vC.$$

In biological systems, advection can arise because of the movement of the cytoplasm, but it can also represent directed transport of molecules, such as the movement of cargo along filaments by processive motors. In general, molecules exhibit both diffusive and advective motion: $j = j_{\text{diff}} + j_{\text{adv}}$, leading to

$$\frac{\partial C}{\partial t} + \nabla(-D\nabla C + vC) = f,$$

which, under the assumption that the diffusion coefficient and the transport velocity are independent of spatial location, leads to the reaction-diffusion-advection equation:

$$\frac{\partial C}{\partial t} = D\nabla^2 C - v\nabla C + f.$$

Being a second-order partial differential, the solution requires an initial condition and two boundary conditions. Common choices for the latter include periodic (e.g., in models of closed boundaries) or no-flux (to describe the impermeability of membranes) assumptions.

Measuring Diffusion Coefficients

Invariably, solving the reaction-diffusion equation requires knowledge of the diffusion coefficient of the molecule. Experimentally, this can be done in a number of ways. In fluorescence recovery after photobleaching (FRAP), a laser is used to photobleach normally fluorescent molecules in a specific area of the cell. As these “dark” molecules are replaced by fluorescent molecules from non-bleached areas, the fluorescent intensity of the bleached area recovers. Higher diffusion leads to faster recovery. The time to half recovery, $\tau_{1/2}$, can be used to estimate D . If recovery occurs by lateral diffusion, then

$$D = \frac{r_0^2 \gamma}{4\tau_{1/2}}$$

where r_0 is the $1/e^2$ radius of the Gaussian profile laser beam and γ is a parameter that depends on the extent of photobleaching, which ranges from 1 to 1.2 (Chen et al. 2006).

These days, it is increasingly common to measure lateral diffusion coefficients by observing the trajectory of single molecules. A molecule with diffusion coefficient D undergoing Brownian motion in a two-dimensional environment is expected to have mean-square displacement (MSD) equal to

$$\langle r^2 \rangle = 4Dt.$$

Thus, the coefficient D can be obtained by measuring how the MSD changes as a function of the time interval t . This method can also show if the molecule is undergoing advection in which case

$$\langle r^2 \rangle = 4Dt + v^2 t^2.$$

This super-diffusive behavior can be seen in the concave nature of the plot of $\langle r^2 \rangle$ against t . This plot will also reveal barriers to diffusion. For example, if the molecule is confined to move in a circular region of radius a , then, as t increases, $\langle r^2 \rangle$ cannot exceed a^2 .

Both these methods work best for molecules diffusing on a membrane. For molecules diffusing in the cytoplasm, the three-dimensional imaging required is considerably more difficult, particularly since the diffusion of particles in the cytoplasm ($D \sim 1\text{--}10 \mu\text{m}^2 \text{s}^{-1}$) is usually orders of magnitude greater than for membrane-bound proteins ($D \sim 0.01\text{--}0.1 \mu\text{m}^2 \text{s}^{-1}$). In this case, an analytical expression can be used to estimate the diffusion coefficient. The diffusion coefficient of a spherical particle of radius r moving in a low Reynolds number liquid with viscosity η is given by the Stokes-Einstein equation:

$$D = \frac{k_B T}{6\pi\eta r}.$$

The exact viscosity of the cell is unknown, but estimates that η is approximately five times that of water lead to diffusion coefficients of cytoplasmic proteins that match those measured using FRAP.

Diffusion-Limited Reaction Rates

Even in compartments that are considered well stirred, the diffusion of molecules is necessary for reactions to take place. In particular, before two molecules can react, they must come together. To see how diffusion influences this, suppose that spherical molecules of species A and B with radii r_A and r_B , respectively, come together to form a complex AB at a rate k_d . This rate represents the likelihood that molecules of A and B collide at random and hence will depend on the diffusion properties of the two species. The molecules in this complex can dissociate at rate k'_d or can be converted to species C at rate k_r . Thus, the overall reaction involves two steps:

Assuming that the system is at quasi-steady-state, that is, the concentration of AB is constant, the effective rate of production C is given by

$$k_{\text{eff}} = \frac{k_d k_r}{k'_d + k_r}.$$

There are two regions of operation. If $k'_d \gg k_r$, then $k_{\text{eff}} \approx k_r (k_d/k'_d)$. In this case production is said to be reaction limited. If $k'_d \ll k_r$, then $k_{\text{eff}} \approx k_d$ and production is diffusion limited. In this case, it is possible to find k_d as a function of the species' diffusion coefficients.

Assume that species A is stationary, in which case the effective diffusion is the sum of the two diffusion coefficients: $D = D_A + D_B$. The concentration of species B depends on the distance away from molecules of A . Because we assume that the reaction rate is fast, at the point of contact ($r^* = r_A + r_B$) the concentration is zero since any molecules of AB are quickly converted to C . At the other extreme, as $r \rightarrow \infty$, the concentration approaches the bulk concentration B_0 . According to Fick's law, this concentration gradient causes a flux density given by $j = -D(\partial B/\partial r)$. The total flux into a sphere of radius r is then

$$J = 4\pi r^2 j = -4\pi D r^2 \frac{\partial B}{\partial r},$$

which, at steady state, is constant. Solving this equation for $B(r)$ using the two boundary equations leads to a flux

$$J = -4\pi D B_0 r^*,$$

from which we have that

$$k_d = 4\pi D r^*.$$

A typical value for k_d , using the Einstein-Stokes formula, is

$$\begin{aligned} 4\pi \left(2 \times \frac{k_B T}{6\pi \eta (r^*/2)} \right) r^* &= \frac{8k_B T}{3\eta} \\ &\approx 10^3 \mu\text{m}^{-1} \text{s}^{-1}. \end{aligned}$$

Spatial Patterns

The effect of spatial heterogeneities has been of long interest to developmental biologists, who study how spatial patterns arise. Two distinct models have been proposed to explain how this patterning can arise. Here we introduce these models and discuss their relative merits. Though usually seen as competing models, there is recent evidence suggesting that both models may play complementary roles during development (Reth et al. 2012).

Morphogen Gradients

A morphogen is a diffusible molecule that is produced or secreted at one end of an organism. Diffusion away from the localized source forms a concentration gradient along the spatial dimension. Morphogens are used to control gene expression of cells lying along this spatial domain. Thus, a morphogen gradient gives rise to spatially dependent expression profiles that can account for spatial developmental patterns (Rogers and Schier 2011).

The mathematics behind the formation of a morphogen gradient are relatively straightforward.

The concentration of the morphogen is denoted by $C(x, t)$. There is a constant flux (j_0) at one end ($x = 0$) of a finite one-dimensional domain of length L , but the morphogen cannot exit at the other end. The species diffuses inside the domain and also decays at a rate proportional to its concentration ($f = -kC$). Thus, the concentration is governed by the reaction-diffusion equation:

$$\frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial x^2} - kC,$$

with boundary conditions: $D \frac{\partial C}{\partial x} = -j_0$ at $x = 0$, and $D \frac{\partial C}{\partial x} = 0$ at $x = L$. We focus on the steady state:

$$\frac{d^2 \bar{C}}{dx^2} = \frac{k}{D} \bar{C},$$

so that the initial condition is not important. In this case, the distribution of the species is given by

$$\bar{C}(x) = \frac{\lambda j_0}{D} \frac{\cosh([L - x]/\lambda)}{\sinh(L/\lambda)}.$$

Thus, the shape of the gradient is roughly exponential with parameter $\lambda = \sqrt{D/k}$, known as the dispersion, which specifies the average distance that molecules diffuse into the domain before they are degraded or inactivated. Equally important in determining the gradient, however, is the spatial dimension (L) relative to the dispersion, $\Phi = L/\lambda$, a ratio known as the Thiele modulus. If $\Phi \ll 1$, then the concentration will be approximately homogeneous. Alternatively, $\Phi \gg 1$ leads to a sharp transition close to the boundary where there is flux and a relatively flat concentration thereafter.

Though morphogen gradients are commonly used to describe signaling during development, where the gradient can extend across a number of cells, the mathematics described above are equally suitable for describing concentration gradients of intracellular proteins. In this case, the dimension of the cell has a significant effect on the shape of the gradient (Meyers et al. 2006).

As discussed above, morphogen gradients are established in an open-loop mode. As such, the actual concentration experienced at a point

downstream of the source of the morphogen will vary depending on a number of parameters, including the flux j_0 and the rate of degradation k . Moreover, because the concentration of the morphogen decreases as the distance from the source grows, the relative stochastic fluctuations will increase. How to manage this uncertainty is an active area of research (Rogers and Schier 2011; Lander 2013).

Diffusion-Driven Instabilities

In 1952, Alan Turing proposed a model of how patterns could arise in biological systems (Turing 1952). His interest was in explaining how an embryo, initially spherical, could give rise to a highly asymmetric organism. He posited that the breaking of symmetry could be a result of the change in the stability of the homogeneous state of the network which would amplify small fluctuations inherent in the initial symmetry. Turing sought to explain how these instabilities could arise using only reaction-diffusion systems.

To illustrate how diffusion-driven instabilities can arise, we work with a single two-species linear reaction network:

$$\frac{\partial}{\partial t} \begin{bmatrix} C_1 \\ C_2 \end{bmatrix} = A \begin{bmatrix} C_1 \\ C_2 \end{bmatrix} + \frac{\partial^2}{\partial x^2} D \begin{bmatrix} C_1 \\ C_2 \end{bmatrix}$$

where $A = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}$ specifies the reaction terms and the diagonal matrix $D = \begin{bmatrix} D_1 & 0 \\ 0 & D_2 \end{bmatrix}$ the diffusion coefficients.

We assume that, in the absence of diffusion, the system is stable, so that $\det(A) > 0$ and $\text{trace}(A) < 0$. When considering diffusion in a one-dimensional environment of length L , we must consider the spatial modes, which are of the form $\exp(ikx)$. In this case, stability of the system requires that $\text{trace}(A - q^2 D) < 0$ and $\det(A - q^2 D) > 0$. The former is always true, since $\text{trace}(A - q^2 D) = \text{trace}(A) - q^2(D_1 + D_2) < \text{trace}(A) < 0$. However, the condition on the determinant can fail since

$$\det(A - q^2 D) = D_1 D_2 q^4 - q^2(a_{22} D_1 + a_{11} D_2) + \det(A). \quad (1)$$

Since $\det(A) > 0$, diffusion-driven instabilities can only occur if the term $a_{22}D_1 + a_{11}D_2 > 0$, by which it follows that at least one of a_{11} or a_{22} must be positive. Since $\text{trace}A < 0$, it follows that the diagonal terms must have opposite sign. Usually, it is assumed that $a_{11} > 0$ and that $a_{22} < 0$. Since $\det(A) > 0$, it follows that a_{12} and a_{21} must also have opposite sign.

These requirements in the sign pattern of the two molecules lead to one of two classes of systems. In the first class, known as activator/inhibitor systems, the activator (assume species 1) is autocatalytic ($a_{11} > 0$) and also stimulates the inhibitor ($a_{21} > 0$), which negatively regulates the activator ($a_{12} < 0$). In the other class, known as substrate-depletion systems, a product (species 1) is autocatalytic ($a_{11} > 0$), but in its production consumes ($a_{21} < 0$) the substrate (species 2) whose presence is needed for formation of the product ($a_{12} > 0$). Note that both systems involve an autocatalytic positive feedback loop ($a_{11} > 0$), as well as a negative feedback loop involving both species ($a_{12}a_{21} < 0$).

The stability condition also imposes a necessary condition on the dispersion of the two species, ($\lambda_i = \sqrt{D_i/|a_{ii}|}$), since

$$a_{22}D_1 + a_{11}D_2 > 0 \implies -\lambda_1^2 + \lambda_2^2 > 0$$

Thus, the species providing the negative feedback (inhibitor or substrate) must have higher dispersion ($\lambda_2 > \lambda_1$). This requirement is usually referred to as local activation and long-range inhibition.

These conditions are necessary, but not sufficient. They ensure that the parabola defined by Eq. 1 has real roots. However, when diffusion takes place in finite domains, the parameter q can only take discrete values $q = 2\pi n/L$ for integers n . Thus, for a spatial mode to be unstable, it must be that $\det(A - q^2D) < 0$ at specific values of q corresponding to integers n . If the dimension of the domain is changing, as would be expected in a growing domain, the parameter q^2 will decrease over time suggesting that higher modes may lose stability. Thus, the nature of the pattern may evolve over time.

Over the years, Turing's framework has been a popular model among theoretical biologists and has been used to explain countless patterns seen in biological systems. It has not had the same level of acceptance among biologists, likely because of the difficulty of mapping a complex biological system involving numerous interacting species into the simple nature of the theoretical model (Kondo and Miura 2010).

Summary and Future Directions

Spatial aspects of biochemical signaling are increasingly playing a role in the study of cellular signaling systems. Part of this interest is the desire to explain spatial patterns seen in sub-cellular localizations observed through live cell imaging using fluorescently tagged proteins. The ever-increasing computational power available for simulations is also facilitating this progress. Specially built spatial simulation software, such as the Virtual Cell, is freely available and tailor-made for biological simulations enabling simulation of spatially varying reaction networks in cells of varying size and shape (Cowan et al. 2012).

Of course, cell shapes are not static, but evolve in large part due to the effect of the underlying biochemical system. This requires simulation environments that solve reaction-diffusion systems in changing morphologies. This has received considerable interest in modeling cell motility (Holmes and Edelstein-Keshet 2013).

Another aspect of spatial models that is only now being addressed is the role of mechanics in driving spatially dependent models. For example, it has recently been shown that the interaction between biochemistry and biomechanics can itself drive Turing-like instabilities (Goehring and Grill 2013).

Finally, we note that our discussion of spatially heterogeneous signaling has been based on continuum models. As with spatially invariant systems, this approach is only valid if the number of molecules is sufficiently large that the stochastic nature of the chemical reactions can be

ignored. In fact, spatial heterogeneities may lead to localized spots requiring a stochastic approach, even though the molecule numbers are such that a continuum approach would be acceptable if the cell were spatially homogeneous. The analysis of stochastic interactions in these systems is still much in its infancy and is likely to be an increasingly important area of research (Mahmutovic et al. 2012).

Spectral Factorization

Michael Sebek

Department of Control Engineering, Faculty of Electrical Engineering, Czech Technical University in Prague, Prague 6, Czech Republic

Abstract

For more than half a century, spectral factorization is encountered in various fields of science and engineering. It is a useful tool in robust and optimal control and filtering and many other areas. It is also a nice control-theoretical concept closely related to Riccati equation. As a quadratic equation in polynomials, it is a challenging algebraic task.

Keywords

Controller design · H_2 -optimal control · H_∞ -optimal control · J-spectral factorization · Linear systems · Polynomial · Polynomial equation · Polynomial matrix · Polynomial methods · Spectral factorization

Polynomial Spectral Factorization

As a mathematical tool, the spectral factorization was invented by Wiener in 1940s to find a frequency domain solution of optimal filtering problems. Since then, this technique has turned up numberless applications in system, network and communication theory, robust and optimal control, filtration, prediction and state reconstruction. Spectral factorization of scalar polynomials is naturally encountered in the area of single-input single-output systems.

In the context of continuous-time problems, real polynomials in a single complex variable s are typically used. For such a polynomial $p(s)$, its *adjoint* $p^*(s)$ is defined by

$$p^*(s) = p(-s), \quad (1)$$

which results in flipping all roots across the imaginary axis. If the polynomial is *symmetric*, then $p^*(s) = p(s)$ and its roots are symmetrically placed about the imaginary axis.

The *symmetric spectral factorization* problem is now formulated as follows: Given a symmetric polynomial $b(s)$,

$$b^*(s) = b(s), \quad (2)$$

that is also positive on the imaginary axis

$$b(i\omega) > 0 \text{ for all real } \omega, \quad (3)$$

find a real polynomial $x(s)$, which satisfies

$$x(s)x^*(s) = b(s) \quad (4)$$

as well as

$$x(s) \neq 0, \quad \text{Res} \geq 0. \quad (5)$$

Such an $x(s)$ is then called a *spectral factor* of $b(s)$. By (5), the spectral factor is a stable polynomial in the continuous-time (Hurwitz) sense.

Obviously, (4) is a quadratic equation in polynomials and its stable solution is the desired spectral factor.

Example Given

$$b(s) = 4 + s^4 = (1 + j + s)(1 - j + s) \\ (1 + j - s)(1 - j - s),$$

(4) results in the spectral factor

$$x(s) = 2 + 2s + s^2 = (1 + j + s)(1 - j + s).$$

When the right-hand side polynomial $b(s)$ has some imaginary-axis roots, the problem

formulated strictly as above becomes unsolvable since (3) does not hold and hence (5) cannot be fulfilled. A more relaxed formulation may then find its use requiring only $b(i\omega) \geq 0$ instead of (3) and $x(s) \neq 0$ only for $\text{Res} > 0$ instead of (5). Clearly, the imaginary-axis roots of $b(s)$ must then appear in $x(s)$ and $x^*(s)$ as well.

In the realm of discrete-time problems, one usually encounters *two-sided polynomials*, which are polynomial-like objects (In fact, one can stay with standard one-sided polynomials (either in nonnegative or in nonpositive powers only), if every adjoint $p^*(z)$ is multiplied by proper power of z to create a one-sided polynomial $\bar{p}(z) = p^*(z)z^n$.) with positive and/or negative powers of a complex variable z , such as, for example, $p(z) = z^{-1} + 1 + 2z$. Here, the *adjoint* $p^*(z)$ stands simply for

$$p^*(z) = p(z^{-1}) \quad (6)$$

and the operation results in flipping all roots across the unit circle. If the two-sided polynomial is *symmetric*, then $p^*(z) = p(z)$ and its roots are symmetrically placed about the unit circle.

In its discrete-time version, the spectral factorization problem is stated as follows: Given a symmetric two-sided polynomial $b(z)$ that meets the conditions of symmetry

$$b^*(z) = b(z) \quad (7)$$

and positiveness (here on the unit circle)

$$b(e^{j\omega}) > 0 \text{ real } \omega, \quad -\pi < \omega \leq \pi, \quad (8)$$

find a real polynomial $x(z)$ in nonnegative powers of z to satisfy

$$x(z)x^*(z) = b(z) \quad (9)$$

and

$$x(z) \neq 0, \quad |z| \geq 1. \quad (10)$$

By (10), the spectral factor is a stable polynomial in the discrete-time (Schur) sense.

Example For

$$\begin{aligned}
 b(z) &= 2z^{-2} + 6z^{-1} + 9 + 6z + 2z^2 \\
 &= 2z^{-2}(z + 0.5 + 0.5j)(z + 0.5 - 0.5j) \\
 &\quad (z + 1 + j)(z + 1 - j) \\
 &= 4(z + 0.5 + 0.5j)(z + 0.5 - 0.5j) \\
 &\quad \times (z^{-1} + 0.5 + 0.5j) \\
 &\quad (z^{-1} + 0.5 - 0.5j)
 \end{aligned}$$

(9) yields

$$\begin{aligned}
 x(z) &= 1 + 2z + 2z^2 = 2(z + 0.5 + 0.5j) \\
 &\quad (z + 0.5 - 0.5j)
 \end{aligned}$$

as the desired spectral factor.

When the right-hand side $b(z)$ possesses some roots on the unit circle, this problem turns out to be unsolvable as (8) fails. If necessary, a less restrictive formulation can then be applied replacing (8) by $b(e^{i\omega}) \geq 0$ and with $x(z) \neq 0$ only for $|z| > 1$ instead of (10). Clearly, the unit-circle roots of $b(z)$ must then appear both in $x(z)$ and $x^*(z)$.

When formulated as above, the spectral factorization problem is always solvable and its solution is unique up to the change of sign (if x is a solution, so is $-x$ and no other solutions exist).

Polynomial Matrix Spectral Factorization

Matrix version of the problem has been encountered since 1960s. In the world of continuous-time problems, real polynomial matrices in a single complex variable s are used. For such a real polynomial matrix $P(s)$, its *adjoint* $P^*(s)$ is defined as

$$P^*(s) = P^T(-s). \quad (11)$$

A polynomial matrix $P(s)$ is *symmetric* or, more precisely, *para-Hermitian*, if $P^*(s) = P(s)$. Needless to say, only square polynomial matrices can be symmetric.

The matrix spectral factorization problem is defined as follows: Given a symmetric polynomial matrix $B(s)$,

$$B^*(s) = B(s), \quad (12)$$

that is also positive definite on the imaginary axis

$$B(i\omega) > 0 \quad \text{for all real } \omega, \quad (13)$$

find a square real polynomial matrix $X(s)$, which satisfies

$$X(s)X^*(s) = B(s) \quad (14)$$

and has no zeros in the closed right half plain $\text{Re } s \geq 0$. Such an $X(s)$ is then called a *left spectral factor* of $B(s)$. A *right spectral factor* $Y(s)$ is defined similarly by replacing (14) with

$$Y^*(s)Y(s) = B(s). \quad (15)$$

Example For a symmetric matrix

$$B(s) = \begin{bmatrix} 2 - s^2 & -2 - s \\ -2 + s & 4 - s^2 \end{bmatrix},$$

we have

$$X(s) = \begin{bmatrix} 1.4 + s & -0.2 \\ -1.2 & 1.6 + s \end{bmatrix}$$

as a left spectral factor and

$$Y(s) = \begin{bmatrix} 1 + s & 0 \\ -1 & 2 + s \end{bmatrix}$$

as a right one.

As in the scalar case, less restrictive definitions are sometimes used where the given right-hand side matrix $B(s)$ is only nonnegative definite on the imaginary axis and so the spectral factor is free of zeros in the open right half plain $\text{Re } s > 0$ only.

In the kingdom of discrete-time, *two-sided real polynomial* matrices $P(z)$ are used having in general entries with both positive and negative powers of the complex variable z . For such a matrix, its *adjoint* $P^*(z)$ is defined by

$$P^*(z) = P^T(z^{-1}). \quad (16)$$

Clearly, if $P(z)$ has only nonnegative powers of z , then $P^*(z)$ has only nonpositive powers of z and

vice versa. A square two-sided polynomial matrix $P(z)$ is (*para-Hermitian*) *symmetric* if $P^*(z) = P(z)$.

Here is the discrete-time version of matrix spectral factorization problem. Given a two-sided polynomial matrix $B(z)$ that is symmetric

$$B^*(z) = B(z) \quad (17)$$

and positively definite on the unit circle

$$B(e^{i\omega}) > 0 \quad \text{real } \omega, \quad -\pi < \omega \leq \pi, \quad (18)$$

find a real polynomial matrix $X(z)$ in nonnegative powers of z such that

$$X(z)X^*(z) = B(z) \quad (19)$$

and has no zeros on and outside of the unit circle. Such an $X(z)$ is then called a *left spectral factor* of $B(z)$. A *right* (The right and the left spectral factor are sometimes called the *factor* and the *cofactor*, respectively, but the terminology is not set at all.) *spectral factor* $Y(z)$ is defined similarly by replacing (19) with

$$Y^*(z)Y(z) = B(z) \quad (20)$$

Example A symmetric two-sided polynomial matrix

$$B(z) = \begin{bmatrix} -2z^{-1} + 5 - 2z & 2z^{-1} - 1 \\ -1 + 2z & 2z^{-1} + 6 + 2z \end{bmatrix}$$

has a left spectral factor

$$X(z) \cong \begin{bmatrix} -1.1 + 1.9z & 0.55 \\ -0.8z & 0.95 + 2.1z \end{bmatrix}$$

and a right spectral factor

$$Y(z) = \begin{bmatrix} 2z - 1 & 1 \\ 0 & 1 + 2z \end{bmatrix}.$$

As before, less restrictive formulations are sometimes encountered where the given symmetric $B(z)$ is only nonnegatively definite on the unit

circle and so the spectral factor must have no zeros only outside of the unit circle.

When formulated as above, the matrix spectral factorization problem is always solvable. The spectral factors are unique up to an orthogonal matrix multiple. That is, if X and X' are two left spectral factors of B , then

$$X' = UX \quad (21)$$

where U is a constant orthogonal matrix $UU^T = I$, while if Y and Y' are two right spectral factors of B , then

$$Y' = YV \quad (22)$$

where V is a constant orthogonal matrix $V^T V = I$.

J-Spectral Factorization

In robust control, game theory and several other fields, the symmetric right-hand side in the matrix spectral factorization may have a general signature. With such a right-hand side, standard (positive or nonnegative definite) factorization becomes impossible. Here, a similar yet different *J*-spectral factorization takes its role.

In the context of continuous-time problems, the *J-spectral factorization problem* is formulated as follows. Given a symmetric polynomial matrix $B(s)$,

$$B^*(s) = B(s), \quad (23)$$

find a square real polynomial matrix $X(s)$, which satisfies

$$X(s)JX^*(s) = B(s), \quad (24)$$

where $X(s)$ has no zeros in the open right half plain $\text{Re } s > 0$ and J is a *signature matrix* of the form

$$J = \begin{bmatrix} I_1 & 0 & 0 \\ 0 & -I_2 & 0 \\ 0 & 0 & 0 \end{bmatrix} \quad (25)$$

with I_1 and I_2 unit matrices of not necessarily the same dimensions. The bottom right block of zeros is often missing, yet it is considered here for generality. Such an $X(s)$ is called a *left J-spectral factor* of $B(s)$. A *right J-spectral factor*

is defined by

$$Y^*(s)JY(s) = B(s) \quad (26)$$

instead of (24). For discrete-time problems, the J -spectral factorization is defined analogously.

The J -spectral factorization problem is quite general having standard (either positive or nonnegative) spectral factorization as a particular case. No necessary and sufficient existence conditions appear to be known for J -spectral factorization. A sufficient condition by Jakubovič (1970) states that the problem is solvable if the multiplicity of the zeros on the imaginary axis of each of the invariant polynomials of the right-hand side matrix is even. In particular, this condition is satisfied whenever $\det B(s)$ has no zeros on the imaginary axis. In turn, the condition is violated if any of the invariant factors is not factorable by itself. An example of a nonfactorizable polynomial is $1 + s^2$.

The J -spectral factors are unique up to a J -orthogonal matrix multiple. That is, if X and X' are two left J -spectral factors of B , then

$$X' = UX, \quad (27)$$

where U is a J -orthogonal matrix $UJU^T = J$, while if Y and Y' are two right J -spectral factors of B , then

$$Y' = YV, \quad (28)$$

where V is a J -orthogonal matrix $V^TJV = J$.

Example For

$$B(s) = \begin{bmatrix} 0 & 1-s \\ 1+s & 2-s^2 \end{bmatrix}$$

the signature matrix reads

$$J = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$$

and the right J -spectral factor is

$$Y(s) = \begin{bmatrix} 1+s & \frac{3-s^2}{2} \\ 1+s & \frac{1-s^2}{2} \end{bmatrix}$$

Nonsymmetric Spectral Factorization

Spectral factorization can also be non-symmetric. For a scalar polynomial p (either in s or in z), this means to factor it directly as

$$p = p^+ p^- \quad (29)$$

where p^+ is a stable factor of p (having all its roots either in the open left half plane or inside of the unit disc, depending on the variable type) while p^- is the “remaining” that is unstable factor. Eventual roots of p at the stability boundary either associate to p^+ or to p^- , depending on the application problem at hand.

For a matrix polynomial P , the non-symmetric factorization is naturally twofold: Either

$$P = P^+ P^- \quad (30)$$

or

$$P = P^- P^+. \quad (31)$$

For scalar polynomials, symmetric and non-symmetric spectral factors are closely related. Given p and having computed a symmetric factor x for pp^* as in (4) or (9) to get

$$x^*x = p^*p \quad (32)$$

Then

$$p^+ = \gcd(p, x) \quad \text{and} \quad p^- = \gcd(p, x^*) \quad (33)$$

where $\gcd$ stands for a greatest common divisor. In reverse,

$$x = p^+ (p^-)^* \quad \text{and} \quad x^* = p^- (p^+)^*. \quad (34)$$

Unfortunately, no such relations exist for the matrix case.

Example For example,

$$p(s) = 1 - s^2$$

factorizes into

$$p^+(s) = 1 + s, \quad p^-(s) = 1 - s$$

while for

$$P(s) = \begin{bmatrix} 1 + s & 0 \\ 1 + s^2 & 1 - s \end{bmatrix}$$

we have

$$P^-(s) = \begin{bmatrix} 1 & 1 \\ s & 1 \end{bmatrix}, \quad P^+(s) = \begin{bmatrix} s & -1 \\ 1 & 1 \end{bmatrix}.$$

Algorithms and Software

Spectral factorization is a crucial step in the solution of various control, estimation, filtration, and other problems. It is no wonder that a variety of methods has been developed over the years for the computation of spectral factors. The most popular ones are briefly mentioned here. For details on particular algorithms, the reader is referred to the papers recommended for further reading.

Factor Extraction Method

If all roots of the right-hand side polynomial are known, the factorization becomes trivial. Just write the right-hand side as a product of first and second order factors and then collect the stable ones to create the stable factor. If the roots are not known, one can first enumerate them and then proceed as above. Somewhat surprisingly, a similar procedure can be used for the matrix case. To every zero, a proper matrix factor must be extracted. For further details, see Callier (1985) or Henrion and Sebek (2000).

Bauer's Algorithm

This procedure is an iterative scheme with linear rate of convergence. It relies on equivalence between the polynomial spectral factorization

and the Cholesky factorization of a related infinite-dimensional Toeplitz matrix. For further details, see Youla and Kazanjian (1978).

Newton-Raphson Iterations

An iterative algorithm with quadratic convergence rate based on consecutive solutions of symmetric linear polynomial Diophantine equations. It is inspired by the classical Newton's method for finding a root of a function. To learn more, read Davis (1963), Ježek and Kučera (1985), Vostrý (1975).

Factorization via Riccati Equation

In state-space solution of various problems, an algebraic Riccati equation plays the role of spectral factorization. It is therefore not surprising that the spectral factor itself can directly be calculated by solution of a Riccati equation. For further info, see e.g. Šebek (1992).

FFT Algorithm

This is the most efficient and accurate procedure for factorization of scalar polynomials with very high degrees (in orders of hundreds or thousands). Such polynomials appear in some special problems of signal processing in advanced audio applications involving inversions of dynamics of loudspeakers or room acoustics. The algorithm is based on the fact that logarithm of a product (such as the spectral factorization equation) turns into a sum of logarithms of particular entries. For details, see Hromčík and Šebek (2007)

All the procedures above are either directly programmed or can be easily composed from the functions of *Polynomial Toolbox for Matlab*, which is a third-party Matlab toolbox for polynomials, polynomial matrices and their applications in systems, signals, and control. For more details on the toolbox, visit www.polyx.com.

Consequences and Comments

Polynomial and polynomial matrix spectral factorization is an important step when frequency domain (polynomial) methods are used for optimal and robust control, filtering, estimation, or

prediction. Numerous particular examples can be found throughout this Encyclopedia as well as in the textbooks and papers recommended for further reading below.

Spectral factorization of rational functions and matrices is an equally important topic but it is omitted here due to lack of space. Inquiring readers are referred to the papers Oara and Varga (2000) and Zhong (2005).

Stability and Performance of Complex Systems Affected by Parametric Uncertainty

Boris Polyak and Pavel Shcherbakov
Institute of Control Science, Moscow, Russia

Abstract

Uncertainty is an inherent feature of all real-life complex systems. It can be described in different forms; we focus on the parametric description. The simplest results on stability of linear systems under parametric uncertainty are the Kharitonov theorem, edge theorem, and graphical tests. More advanced results include sufficient conditions for robust stability with matrix uncertainty, LMI tools, and randomized methods. Similar approaches are used for robust control synthesis, where performance issues are crucial.

Keywords

Edge theorem · Kharitonov theorem · Linear systems · Matrix · Parametric uncertainty and robustness · Quadratic stability · Randomized methods · Robust and optimal design · Robust stability · Tsytkin–polyak plot

Introduction

Mathematical models for systems and control are often unsatisfactory due to the incompleteness of the parameter data. For instance, the ideas of off-line optimal control can only be applied to real systems if all the parameters, exogenous disturbances, state equations, etc. are known precisely. Moreover, feedback control also requires a detailed information which is not available in most cases. For example, to drive a car with four-wheel control, the controller should be aware of the total weight, location of the center of gravity, weather conditions, and highway properties as well as many other data which may not be known. In that respect, even such a relatively simple real-life system can be considered a *complex* one; in such circumstances, control under uncertainty is a highly important issue.

The focus in this entry is on the *parametric uncertainty*; other types of uncertainty can be treated in more general models of robustness. This topic became particularly popular in the control community in the mid- to late 1980s of the previous century; at large, the results of this activity have been summarized in the monographs (Ackermann 1993; Barmish 1994; Bhattacharyya et al. 1995).

We start with problems of stability of polynomials with uncertain parameters and present the simplest robust stability results for this case together with the most important machinery. Next, we consider stability analysis for the matrix uncertainty; most of the results are just sufficient conditions. We present some useful tools for the analysis, such as the LMI technique and randomized methods. Robust control under parametric uncertainty is the next step; we briefly discuss several problem formulations for this case.

Stability of Linear Systems Subject to Parametric Uncertainty

Consider the closed-loop linear, time-invariant continuous time state space system

$$\dot{x} = Ax, \quad x(0) = x_0, \quad (1)$$

where $x(t) \in \mathbb{R}^n$ is the state vector, x_0 is an arbitrary finite initial condition, and $A \in \mathbb{R}^{n \times n}$ is the state matrix. The system is stable (i.e., no matter what x_0 is, the solutions tend to zero as $t \rightarrow \infty$) if and only if all eigenvalues λ_i of the matrix A have negative real parts:

$$\operatorname{Re} \lambda_i < 0, \quad i = 1, \dots, n, \quad (2)$$

in which case, A is said to be a *Hurwitz* matrix. If it is known precisely, checking condition (2) is immediate. For instance, one might compute the characteristic polynomial

$$\begin{aligned} p(s) &= \det(sI - A) \\ &= a_0 + a_1s + \dots + a_{n-1}s^{n-1} + s^n \end{aligned} \quad (3)$$

of A (here, I is the identity matrix) and use any of the stability tests (e.g., the Routh algorithm, Routh–Hurwitz test, and graphical tests such as the Mikhailov plot or Hermite–Biehler theorem); see Gantmacher (2000). Alternatively, the eigenvalues can be directly computed using the currently available software, such as MATLAB.

However, things get complicated if the knowledge of the matrix A is incomplete; for instance, it can depend on the (real) parameters $q = (q_1, \dots, q_m)$ which take arbitrary values within the given intervals:

$$A = A(q), \quad \underline{q}_i \leq q_i \leq \bar{q}_i, \quad i = 1, \dots, m. \quad (4)$$

In that case, we arrive at the *robust stability problem*; i.e., the goal is to check if condition (2) holds for *all matrices* in the family (4).

The two main components of any robust stability setup are the *feasible set* $\mathcal{Q} \subset \mathbb{R}^\ell$, in which the uncertain parameters are allowed to take their values (usually a ball in some norm, e.g., the box as in (4)), and the *uncertainty structure*, which defines the functional dependence of the coefficients on the uncertain parameters. Of the

most interest are the affine and multiaffine dependence; typically, more general situations are hard to handle.

Simple Solutions

In some cases, the robust stability problem admits a simple solution. Perhaps the most striking example is the so-called Kharitonov theorem (Kharitonov 1978); also see Barmish (1994), where this seminal result is referred to as a *spark* because of its transparency and elegance.

Namely, consider the *interval polynomial family*

$$\begin{aligned} \mathcal{P} &= \{p(s) = q_0 + q_1s + \dots + q_ns^n, \\ &\quad \underline{q}_i \leq q_i \leq \bar{q}_i, \quad i = 0, \dots, n\}, \end{aligned} \quad (5)$$

where the coefficients q_i are allowed to take values in the respective intervals *independently of each other*, and distinguish the following four elements in this family:

$$p_1(s) = \underline{q}_0 + \underline{q}_1s + \bar{q}_2s^2 + \bar{q}_3s^3 + \dots$$

$$p_2(s) = \underline{q}_0 + \bar{q}_1s + \bar{q}_2s^2 + \underline{q}_3s^3 + \dots$$

$$p_3(s) = \bar{q}_0 + \bar{q}_1s + \underline{q}_2s^2 + \underline{q}_3s^3 + \dots$$

$$p_4(s) = \bar{q}_0 + \underline{q}_1s + \underline{q}_2s^2 + \bar{q}_3s^3 + \dots$$

By the Kharitonov theorem, the interval family (5) is robustly stable (i.e., all polynomials in (5) are Hurwitz having all roots with negative real parts) if and only if the *four Kharitonov polynomials*, p_1 , p_2 , p_3 , and p_4 , are Hurwitz.

A simple and transparent proof of this result can be obtained using the *value set concept* (Zadeh and Desoer 1963) and the *zero exclusion principle* (Frazer and Duncan 1929), the two general tools which are in the basis of many results in the area of robust stability. We illustrate these concepts via robust stability of polynomials.

Given the uncertain polynomial family

$$\mathcal{P}(s, \mathcal{Q}) = \{p(s, q), \quad q \in \mathcal{Q}\},$$

the set

$$\mathcal{V}(\omega) = \{p(j\omega, q) : \omega \geq 0, q \in \mathcal{Q}\}$$

is referred to as the *value set*, which is, by definition, the set on the complex plane obtained by fixing the argument s to be $j\omega$ for a certain value of ω and letting the uncertain parameter vector q sweep the feasible domain.

The zero exclusion principle states that, under certain regularity requirements, the uncertain polynomial family is robustly stable if and only if it contains a stable element and the following condition holds:

$$0 \notin \mathcal{V}(\omega) \quad \forall \omega \geq 0. \quad (6)$$

To use this machinery, one has to be able to compute efficiently the value set and check condition (6). For the interval family (5), the value set can be shown to be the rectangle with coaxial edges and the vertices being the values of the four Kharitonov polynomials; see Fig. 1.

Being an extremely propelling result, the Kharitonov theorem is not free of drawbacks. First of all, it is not capable of determining the maximal lengths of the uncertainty intervals that retain the robust stability. This relates to an

important notion of *robust stability margin*; for simplicity, we define this quantity for the case of the interval family (5). Namely, introduce the *nominal polynomial* $p_0(s)$ with coefficients

$$q_i^0 = (\bar{q}_i + \underline{q}_i)/2,$$

and the *scaling factors*

$$\alpha_i = (\bar{q}_i - \underline{q}_i)/2$$

for the deviations of the coefficients. Then the robust stability margin $r_{\max}$ is defined as follows:

$$r_{\max} = \sup\{r : p(s, q) \text{ (5) is stable } \forall q_i :$$

$$|q_i - q_i^0| \leq r\alpha_i, \quad i = 1, \dots, n\}.$$

Another drawback of the Kharitonov result is its inapplicability to the discrete-time case (Schur stability of polynomials).

A more flexible graphical test for robust stability uses the so-called Tsytkin–Polyak plot (Tsytkin and Polyak 1991), which is defined as the parametric curve on the complex plane:

$$z(\omega) = x(\omega) + jy(\omega), \quad j = \sqrt{-1}; \quad 0 \leq \omega < \infty,$$

Stability and Performance of Complex Systems Affected by Parametric Uncertainty,
Fig. 1 The Kharitonov rectangular value set

where

$$x(\omega) = \frac{q_0^0 - q_2^0 \omega^2 + \dots}{\alpha_0 + \alpha_2 \omega^2 + \dots},$$

$$y(\omega) = \frac{q_1^0 - q_3^0 \omega^2 + \dots}{\alpha_1 + \alpha_3 \omega^2 + \dots}.$$

Then, by the Tsytkin–Polyak criterion, the polynomial family (5) is robustly stable if and only if the following conditions hold: (i) $q_0^0 > \alpha_0$, $q_n^0 > \alpha_n$, and (ii) as ω changes zero to infinity, the curve $z(\omega)$ goes consecutively through n quadrants in the counterclockwise direction and does not intersect the unit square with the vertices $(\pm 1, \pm j)$.

Unlike the Kharitonov theorem, with this test, the robust stability margin of family (5) can be determined as the size of the maximal square inscribed in the curve $z(\omega)$; see Fig. 2. Moreover, with minor modifications, this test applies to *dependent uncertainty structures* where the coefficient vector $q = (q_0, \dots, q_n)^\top$ is confined to a ball in ℓ_p -norm, not to a *box* as in (5).

On top of that, the Tsytkin–Polyak plot can be built for discrete-time systems which do not admit any counterparts of the Kharitonov theorem.

It is fair to say that interval polynomial families are an idealization, since the coefficients of the characteristic polynomial can hardly be

thought of as the physical parameters of the real-world system. As a step toward more realistic formulations, consider the *affine polynomial family* of the form

$$P(s) = p_0(s) + \sum_{i=1}^m q_i p_i(s), |q_i| \leq 1, i=1, \dots, m, \quad (7)$$

where p_i are the given polynomials and the q_i s are the uncertain parameters (clearly, they can be scaled to take values in the segment $[-1, 1]$). The famous *edge theorem* (Bartlett et al. 1988) claims that checking the robust stability of such a family is equivalent to checking the *edges* of the uncertainty box, i.e., the points $q \in \mathbb{R}^m$ with all but one components being fixed to ± 1 , while the “free” coordinate varies in $[-1, 1]$.

Complex Solutions

Obviously, the affine model (7) covers just a small part of problems with parametric uncertainty. Closed-form solutions cannot be obtained in the general case; however, many important classes of systems can be analyzed efficiently.

Thus, in the engineering practice, *block diagram description* of systems is often more convenient than differential equations of the form (1). The blocks are associated with typical elements such as amplifiers, integrators, lag elements, and

Stability and Performance of Complex Systems Affected by Parametric Uncertainty, Fig. 2 The Tsytkin–Polyak plot

oscillators, which are connected in a certain circuit. In this case, transfer functions are the most adequate tool for dealing with such systems. For instance, the transfer function of the lag element is given by

$$W(s) = 1/(Ts + 1),$$

where the scalar T is the *time constant* of the element. In terms of differential equations, this means that the input $u(t)$ of a block and its output $x(t)$ satisfy the equation $T\dot{x} + x = u$.

Assume now we have a set of m cascade connected elements with uncertain time constants

$$\underline{T}_i \leq T_i \leq \bar{T}_i, \quad i = 1, \dots, m, \quad (8)$$

with known lower and upper bounds. The characteristic polynomial of such a connection embraced by the feedback with *gain* k is known to have the form

$$p(s) = k + (1 + T_1 s) \cdots (1 + T_m s). \quad (9)$$

Hence, the robust stability problem reduces to checking if all polynomials (9) with constraints (8) are Hurwitz. Note that the coefficients of such a polynomial depend *multilinearly* on the uncertain parameters T_i (cf. linear dependence in (7)), making the problem much more complicated.

The solution of the problem above was obtained in Kiselev et al. (1997) for many important special cases; the closely related problem of finding the “critical gain” (the maximal value of k retaining the robust stability) was also addressed.

Using the similar technique, closed-form solutions can be obtained for a number of similar problems such as robust sector stability, robust stability of distributed systems, and robust D -decomposition, to name just a few.

Difficult Problems: Possible Approaches

In spite of the apparent progress obtained in the area of parametric robustness, the list of unsolved problems is still quite large. Moreover, some of

the formulations were shown to be NP-hard, making it hard to believe that any efficient solution methods will ever be found.

One of such fundamental problems is robust stability of the *interval matrix*. Specifically, assume that the entries a_{ij} of the matrix A in (1) are interval numbers

$$\underline{a}_{ij} \leq a_{ij} \leq \bar{a}_{ij}, \quad i, j = 1, \dots, n;$$

the problem is to check if the interval matrix is robustly stable, i.e., if the eigenvalues of all matrices in this family have negative real parts. Numerous attempts to prove a Kharitonov-like theorem for matrices have failed, and the results by Nemirovskii (1994) on NP-hardness showed that these generalizations are not possible. It was also shown that the edge theorem for matrix families is not valid. The other NP-hard problems in robustness include the analysis of systems with interval delays, parallel connection of uncertain blocks, problem (9)–(8) with nested segments $[\underline{T}_i, \bar{T}_i]$, and others.

However, a change in the statement of the problem often allows for simple and elegant solutions. We mention three fruitful reformulations.

In the first approach, the uncertain parameters are assumed to have random rather than deterministic nature; for instance, they are assumed to be uniformly distributed over the respective intervals of uncertainty. We next specify an acceptable tolerance ε , say $\varepsilon = 0.01$, and check if the resulting random family of polynomials is stable with probability no less than $(1 - \varepsilon)$; see Tempo et al. (2013) for a comprehensive exposition of such a *randomized approach to robustness*; also see Polyak and Shcherbakov (2018) for a more recent development.

In many of the NP-hard robustness problems, such a reformulation often leads to exact or approximate solutions. Moreover, the randomized approach has several attractive properties even in the situations where the deterministic solution is available. Indeed, the deterministic statements of robustness problems are minimax; hence, the answer is dictated by the “worst” element in the family, whereas these critical values of the uncertain parameters are rather

unlikely to occur. Therefore, by neglecting a small risk of violation of the stability, the admissible domains of variation of the parameters may be considerably extended. This effect is known as the *probabilistic enhancement of robustness margins*; it is particularly tangible for the large number of the parameters. Another attractive property of the randomized approach is its low computational complexity which only slowly grows with increase of the number of uncertain parameters.

To illustrate, let us turn back to problem (9)–(8) and use the value set approach. In the considered problem, this set can be efficiently built.

Assume now that the parameters T_i are independent random variables uniformly distributed over the respective segments (8) and consider the random variable

$$\eta = \eta(\omega) = \log(p(j\omega) - k) = \sum_{i=1}^m \log(1 + j\omega T_i).$$

The right-hand side of the last relation is the sum of independent complex-valued random variables; for m large, its behavior obeys the central limit theorem, so that the probability that η belongs to the respective *confident ellipse* $\mathcal{E} = \mathcal{E}(\omega)$ is close to unity. In other words, we have

$$p(j\omega) \approx k + e^{\mathcal{E}} \doteq \mathcal{G}(\omega),$$

and the set $\mathcal{G}(\omega)$ is referred to as a *probabilistic predictor* of the value set $\mathcal{V}(\omega)$; it is the shifted set of points of the form e^z , $z \in \mathcal{E} \subset \mathbb{C}$. The predictor $\mathcal{G}(\omega)$ constitutes a small portion of the deterministic value set $\mathcal{V}(\omega)$, yielding the probabilistic enhancement of the robustness margin.

Note also that the computation of $\mathcal{E}$ and $e^{\mathcal{E}}$ is nearly trivial, and, in contrast to the construction of the true value set $\mathcal{V}$, the complexity does not grow with increase of m .

The *second approach* to solving “hard” problems in robust stability relates to the notion of *superstability* (Polyak and Shcherbakov 2002). The matrix A of system (1) (and the system itself) is said to be *superstable*, if its entries a_{ij} , $i, j = 1, \dots, n$, satisfy the relations

$$a_{ii} < 0, \quad \min_i (-a_{ii} - \sum_{j \neq i} |a_{ij}|) = \sigma > 0.$$

The following estimate holds for the solutions of the superstable system (1):

$$\|x(t)\|_{\infty} \leq \|x(0)\|_{\infty} e^{-\sigma t},$$

i.e., it is stable, and the (nonsmooth) function $\|x\|_{\infty}$ is a Lyapunov function for the system. Since the condition of superstability is formulated in terms of linear inequalities on the entries of A , checking robust superstability of affine (and in particular, interval) matrix families is immediate. Similar situation holds for so-called positive systems.

The *third approach* to robustness analysis relates to *quadratic stability* (Leitmann 1979; Boyd et al. 1994). Namely, a family of systems is said to be *robustly quadratically stable* if it possesses a common quadratic Lyapunov function $V(x) = x^{\top} P x$ with positive definite matrix P . In other words, an uncertain family of matrices $A(q)$, $q \in \mathcal{Q}$ has to satisfy the following set of the matrix Lyapunov-type inequalities:

$$A(q)P + PA(q)^{\top} < 0, \quad q \in \mathcal{Q}, \text{ and } P > 0,$$

where the symbols $<$, $>$ stand for the sign definiteness of a matrix.

The inequality above is referred to as a *linear matrix inequality* (LMI), (Boyd et al. 1994); there exist both efficient numerical methods for solving such inequalities (*interior point methods*) and various software, e.g., MATLAB. This approach can be directly applied at least in the following two cases: (i) the set $\mathcal{Q}$ contains a finite number of points, and (ii) $\mathcal{Q}$ is a polyhedron, and the dependence $A(q)$ is affine. In the general setup or in the high-dimensional problems, randomized methods can be employed.

Finding the *quadratic robust stability margin* (by analogy with the stability margin, this is the maximum span of the feasible set $\mathcal{Q}$ that allows for the existence of the common Lyapunov function) in this problem is also possible; it reduces to the minimization of a linear function over the solutions of a similar LMI.

Note that the approaches based on superstability and quadratic stability provide only sufficient conditions for robustness.

Robust Control

So far, of our primary interest was in assessing the robust stability of a closed-loop system with synthesized linear feedback. A more important problem is to *design* a controller that makes the closed-loop system robustly stable and guarantees certain *robust performance* of the system.

Robust Stabilization

Let the linear system

$$\dot{x} = A(q)x + Bu$$

depend on the vector $q \in \mathcal{Q}$ of uncertain parameters. In the simplest form, the problem of *robust stabilization* consists in finding the linear static state feedback

$$u = Kx$$

that guarantees the robust stability of the closed-loop system. Alternatively, static or dynamic *output* robustly stabilizing controllers can be considered in the situations where only the linear output $y = Cx$ of the system is available, but not the complete state vector x .

If the number of controller parameters to be tuned is small (which is the case for PI or PID controllers), then the design can be accomplished using the *D-decomposition technique*.

In the general formulation, the problem of robust design is complicated; it can, however, be addressed with the use of randomized methods (Tempo et al. 2013). Other plausible approaches include superstability and quadratic stability; respectively, the problem reduces to solving linear programs or linear matrix inequalities in the coefficients of the controller.

Robust Performance

Needless to say, the robust stabilization problem is not the only one in the area of optimal control. As a rule, a certain cost function is always involved (say, integral quadratic), and its desired

value should be guaranteed for all admissible values of the uncertain parameters. Moreover, robust stability is a necessary condition for such a guaranteed estimate to exist. This sort of problems can often be cast in the form of LMIs which must be satisfied for all admissible values of the parameters. Such robust LMIs can be solved either directly or using various randomized techniques presented in Tempo et al. (2013).

Summary and Future Directions

In spite of the considerable progress attained in the parametric robustness of complex systems, this topic is still a vivid and active research area. To date, randomization, superstability, and quadratic stability present the most efficient and diverse tools for the analysis and design of systems affected by parametric uncertainty.

In this article, we paid no attention to several related issues that might be worth discussing. Among them is robustness assessment in discrete-time systems, circular (rather than interval) uncertainty, additive norm-bounded matrix uncertainty, and, importantly, parameter-dependent Lyapunov functions.

Stability Theory for Hybrid Dynamical Systems

Andrew R. Teel
Electrical and Computer Engineering
Department, University of California, Santa
Barbara, CA, USA

Abstract

This entry provides a short introduction to modeling of hybrid dynamical systems and then focuses on stability theory for these systems. It provides definitions of asymptotic stability, basin of attraction, and uniform asymptotic stability for a compact set. It points out

mild assumptions under which different characterizations of asymptotic stability are equivalent, as well as when an asymptotically stable compact set exists. It also summarizes necessary and sufficient conditions for asymptotic stability in terms of Lyapunov functions.

Keywords

Asymptotic stability · Basin of attraction · Hybrid system · Lyapunov function

Introduction

A hybrid dynamical system combines continuous change and instantaneous change. Instantaneous change is the only type of change available for variables like counters, switches, and logic variables. Instantaneous change may also be a good approximation of what occurs to velocities in mechanical systems at the time of an impact with a wall, floor, or some other rigid body. At other times, velocities evolve continuously. Continuous change is also natural for position variables, continuous timers, and voltages and currents. For mathematical convenience, it is typical in the analysis of hybrid dynamical systems to embed all of these variables into a Euclidean space, with the understanding that many points in the state space will never be reached. For example, a logic variable that naturally takes values in the set {off, on} is typically embedded in the real number line where its two distinct values are associated with two distinct numbers, the only numbers that this variable will visit during its evolution.

A finite-dimensional dynamical system that exhibits continuous change exclusively is typically modeled by an ordinary differential equation, or sometimes a more flexible differential inclusion. A system that exhibits purely instantaneous change is typically modeled by a difference equation or inclusion. Consequently, a hybrid dynamical system combines a differential equation or inclusion with a difference equation or inclusion. A big part of the modeling effort for hybrid systems is directed at determining which type of evolution should be allowed at each point

in the state space. To this end, subsets of the state space are specified where each type of behavior is allowed.

Though the behavior of a hybrid dynamical system can be quite complex and nonconventional, it is still reasonable to ask the same stability questions for them that might be asked about classical differential or difference equations. Moreover, the same stability analysis tools that are used for classical systems are also quite useful for hybrid dynamical systems. The emphasis of this entry is on basic stability theory for hybrid dynamical systems, focusing on definitions and tools that also apply to classical systems.

Mathematical Modeling

System Data

A hybrid dynamical system with state x belonging to a Euclidean space $\mathbb{R}^n$ combines a differential equation or inclusion, written formally as $\dot{x} = f(x)$ or $\dot{x} \in F(x)$, with a difference equation or inclusion $x^+ = g(x)$ or $x^+ \in G(x)$, where $\dot{x}$ indicates the time derivative and x^+ indicates the value after an instantaneous change. The mapping f or F is called the *flow map*, while the mapping g or G is called the *jump map*. A complete model also specifies where in the state space continuous evolution is allowed and where instantaneous change is allowed. The set where continuous evolution is allowed is called the *flow set* and is denoted C , whereas the set where instantaneous change is allowed is called the *jump set* and is denoted D . The overall model, using inclusions for generality, is written formally as

$$x \in C \quad \dot{x} \in F(x) \quad (1a)$$

$$x \in D \quad x^+ \in G(x). \quad (1b)$$

Solutions

It is natural for solutions of (1) to be functions of two different types of time: a variable t that keeps track of the amount of ordinary time that has elapsed and a variable j that counts the number of

jumps. There is a special structure to the types of domains that are allowed. A *compact hybrid time domain* is a set $E \subset \mathbb{R}_{\geq 0} \times \mathbb{Z}_{\geq 0}$, that is, a subset of the product of the nonnegative real numbers and the nonnegative integers, of the form

$$E = \bigcup_{i=0}^J ([t_i, t_{i+1}] \times \{i\})$$

for some $J \in \mathbb{Z}_{\geq 0}$ and some sequence of non-decreasing times $0 = t_0 \leq t_1 \leq \dots \leq t_{J+1}$. It is possible for several of these times to be the same, which would correspond to more than one jump at the given time. A *hybrid time domain* is a set $E \subset \mathbb{R}_{\geq 0} \times \mathbb{Z}_{\geq 0}$ such that for each $(T, J) \in E$, the set $E \cap ([0, T] \times \{0, \dots, J\})$ is a compact hybrid time domain. In contrast to a compact hybrid time domain, a hybrid time domain may have an infinite number of intervals, or it may have a finite number of intervals with the last one being unbounded or of the form $[t_J, t_{J+1})$; that is, it may be open on the right. A *hybrid arc* is a function x , defined on a hybrid time domain, such that $t \mapsto x(t, j)$ is locally absolutely continuous for each j ; in particular, $t \mapsto x(t, j)$ is differentiable for almost every t where it is defined, and this mapping is the integral of its derivative. The notation “dom x ” denotes the domain of x . Finally, a hybrid arc is a *solution* of (1) if the following two properties are satisfied:

1. For $\varepsilon > 0$, $(s, j), (s + \varepsilon, j) \in \text{dom } x$ implies that $x(t, j) \in C$ and $\dot{x}(t, j) \in F(x(t, j))$ for almost all $t \in [s, s + \varepsilon]$.
2. $(t, j), (t, j+1) \in \text{dom } x$ implies that $x(t, j) \in D$ and $x(t, j+1) \in G(x(t, j))$.

For a hybrid system with no flow dynamics, each solution has a time domain of the form $\{0\} \times \{0, \dots, J\}$ for some $J \in \mathbb{Z}_{\geq 0}$ or $\{0\} \times \mathbb{Z}_{\geq 0}$. For a hybrid system with no jump dynamics, each solution has a time domain of the form $[0, \infty) \times \{0\}$, $[0, T] \times \{0\}$, or $[0, T) \times \{0\}$ for some $T \geq 0$. No assumptions are made in this entry to guarantee existence of nontrivial solutions since stability theory does not hinge

on existence of solutions; rather, it simply makes statements about the behavior of solutions when they exist. To ensure robustness of various stability properties, the following basic regularity assumptions are usually imposed.

Assumption 1 The data (C, F, D, G) satisfy the following conditions:

1. The sets C and D are closed.
2. The set-valued mapping F is outer semicontinuous, locally bounded, and $F(x)$ is nonempty and convex for each $x \in C$.
3. The set-valued mapping G is outer semicontinuous, locally bounded, and $G(x)$ is nonempty for each $x \in D$.

To elaborate further, a set-valued mapping, like F , is said to be *outer semicontinuous* if for each convergent sequence $\{(x_i, y_i)\}_{i=0}^{\infty}$ that satisfies $y_i \in F(x_i)$ for all $i \in \mathbb{Z}_{\geq 0}$, its limit, denoted (x, y) , satisfies $y \in F(x)$. It is said to be *locally bounded* if for each bounded set $K_1 \subset \mathbb{R}^n$ there exists a bounded set $K_2 \subset \mathbb{R}^n$ such that, for every $x \in K_1$, every $y \in F(x)$ belongs to K_2 ; the latter condition is sometimes written $F(K_1) \subset K_2$. If C is closed, f is a function $f : C \rightarrow \mathbb{R}^n$ that is continuous, and F is a set-valued mapping that has the single value $f(x)$ for each $x \in C$ and is empty for $x \notin C$, then F is outer semicontinuous, locally bounded, and $F(x)$ is nonempty and convex for each $x \in C$.

Stability Theory

Definitions and Relationships

Given a dynamical system, predicting or controlling the system's long-term behavior is of primary importance. A system's long-term behavior may be more complicated than just converging to an equilibrium point. This fact motivates studying stability of and convergence to a set of points. For simplicity, this entry focuses on stability of sets that are *compact*, that is, they are closed and bounded. A variety of stability concepts are defined below. Each of these concepts applies

to continuous-time or discrete-time systems as readily as to hybrid systems.

A compact set $\mathcal{A} \subset \mathbb{R}^n$ is said to be *Lyapunov stable* for (1) if for each $\varepsilon > 0$ there exists $\delta > 0$ such that for every solution of (1), $x(0, 0) \in \mathcal{A} + \delta\mathbb{B}$ implies $x(t, j) \in \mathcal{A} + \varepsilon\mathbb{B}$ for all $(t, j) \in \text{dom } x$, where $\mathcal{A} + \delta\mathbb{B}$ indicates the set of points whose distance to the set $\mathcal{A}$ is less than or equal to δ . In order for a compact set to be Lyapunov stable for (1), it must be *forward invariant* for (1), that is, each solution of (1) with $x(0, 0) \in \mathcal{A}$ satisfies $x(t, j) \in \mathcal{A}$ for all $(t, j) \in \text{dom } x$. However, forward invariance does not necessarily imply Lyapunov stability.

For a compact set $\mathcal{A} \subset \mathbb{R}^n$, its *basin of attraction* for (1), denoted $\mathcal{B}_{\mathcal{A}}$, is the set of points from which each solution to (1) is bounded and each solution to (1) having an unbounded time domain converges to $\mathcal{A}$, the latter being written mathematically as $\lim_{t+j \rightarrow \infty} |x(t, j)|_{\mathcal{A}} = 0$ where $|x(t, j)|_{\mathcal{A}}$ denotes the distance of $x(t, j)$ to the set $\mathcal{A}$. Each point that does not belong to $C \cup D$ belongs to $\mathcal{B}_{\mathcal{A}}$ since there are no solutions from such points. A compact set $\mathcal{A}$ is said to be *attractive* for (1) if its basin of attraction contains a neighborhood of itself, that is, there exists $\varepsilon > 0$ such that $\mathcal{A} + \varepsilon\mathbb{B} \subset \mathcal{B}_{\mathcal{A}}$. A compact set $\mathcal{A}$ is said to be *globally attractive* if $\mathcal{B}_{\mathcal{A}} = \mathbb{R}^n$.

A compact set is said to be *asymptotically stable* for (1) if it is Lyapunov stable and attractive for (1). A compact set is said to be *globally asymptotically stable* for (1) if it asymptotically stable for (1) and $\mathcal{B}_{\mathcal{A}} = \mathbb{R}^n$. It is useful to know that the basin of attraction for an asymptotically stable set is always open.

Theorem 1 Under Assumption 1, if a compact set is asymptotically stable for (1), then its basin of attraction is an open set.

A compact set $\mathcal{A} \subset \mathbb{R}^n$ is said to be *uniformly attractive* for (1) if it is attractive for (1) and for each compact set $K \subset \mathcal{B}_{\mathcal{A}}$ and each $\delta > 0$ there exists $T > 0$ such that for every solution x of (1), $x(0, 0) \in K$ and $t + j \geq T$ imply $x(t, j) \in \mathcal{A} + \delta\mathbb{B}$. A compact set is said to be *uniformly globally attractive* for (1) if it is globally attractive and uniformly attractive for (1). Uniform attractivity goes beyond attractivity

by asking that the amount of time it takes each solution to get close to $\mathcal{A}$ is uniformly bounded over initial conditions in compact subsets of the basin of attraction.

A compact set $\mathcal{A} \subset \mathbb{R}^n$ is said to be *Lagrange stable* relative to an open set $O \supset \mathcal{A}$ for (1) if for each compact set $K_1 \subset O$ there exists a compact set $K_2 \subset O$ such that for every solution of (1), $x(0, 0) \in K_1$ implies $x(t, j) \in K_2$ for all $(t, j) \in \text{dom } x$. In Lagrange stability for the case $O = \mathbb{R}^n$, a bound on the initial conditions is given and a bound on the ensuing solutions must be found; this is in contrast to Lyapunov stability where a bound on the solutions is given and a bound on the initial conditions must be found.

A compact set is said to be *uniformly asymptotically stable* for (1) if it is Lyapunov stable, attractive, Lagrange stable relative to its basin of attraction, and uniformly attractive for (1). A compact set is said to be *uniformly globally asymptotically stable* for (1) if it is uniformly asymptotically stable for (1) and $\mathcal{B}_{\mathcal{A}} = \mathbb{R}^n$. There is no difference between asymptotic stability and uniform asymptotic stability under Assumption 1.

Theorem 2 *Under Assumption 1, a compact set is uniformly asymptotically stable for (1) if and only if it is locally asymptotically stable for (1).*

As noted earlier, forward invariance does not imply Lyapunov stability. However, when coupled with uniform attractivity, Lyapunov stability ensues.

Theorem 3 *Under Assumption 1, a compact set is uniformly asymptotically stable for (1) if and only if it is forward invariant and uniformly attractive for (1).*

Asymptotic stability can be converted to global asymptotic stability by shrinking the flow and jump sets to be compact subsets of the basin of attraction. However, global asymptotic stability of a compact set $\mathcal{A}$ for $x \in C$, $\dot{x} = f(x)$ for each compact set C does not necessarily imply global asymptotic stability of $\mathcal{A}$ for $\dot{x} = f(x)$.

In some situations it is easier to assert the existence of a compact asymptotically stable set than it is to find one explicitly. In this direction, given a

set $X \subset \mathbb{R}^n$, consider the set of points z with the property that there exist a sequence of solutions $\{x_i\}_{i=0}^{\infty}$ to (1) with initial conditions in X and an unbounded sequence of times $\{(t_i, j_i)\}_{i=0}^{\infty}$ with $(t_i, j_i) \in \text{dom } x_i$ for each $i \in \mathbb{Z}_{\geq 0}$ such that $z = \lim_{i \rightarrow \infty} x_i(t_i, j_i)$. This set of points is called the ω -limit set of X for (1) and is denoted $\Omega(X)$.

Theorem 4 *Let Assumption 1 hold. For the system (1), if X is compact and $\Omega(X)$ is nonempty and contained in the interior of X (i.e., there exists $\varepsilon > 0$ such that $\Omega(X) + \varepsilon\mathbb{B} \subset X$), then the set $\Omega(X)$ is compact and uniformly asymptotically stable with basin of attraction containing X and equal to the basin of attraction for X .*

Robustness

A given model (C, F, D, G) may have some mismatch with a physical process that it aims to describe. One way to capture some of this mismatch is to consider the behavior of solutions to a system with inflated data $(C_{\delta}, F_{\delta}, D_{\delta}, G_{\delta})$, $\delta \geq 0$, defined as follows:

$$C_{\delta} := \{x \in \mathbb{R}^n : (x + \delta\mathbb{B}) \cap C \neq \emptyset\} \quad (2a)$$

$$F_{\delta}(x) := \overline{\text{co}}F((x + \delta\mathbb{B}) \cap C) + \delta\mathbb{B} \quad (2b)$$

$$D_{\delta} := \{x \in \mathbb{R}^n : (x + \delta\mathbb{B}) \cap D \neq \emptyset\} \quad (2c)$$

$$G_{\delta} := G((x + \delta\mathbb{B}) \cap D) + \delta\mathbb{B}. \quad (2d)$$

The notation $x + \delta\mathbb{B}$ indicates a closed ball of radius δ centered at the point x . Evaluating a set-valued mapping at a set of points means to collect all vectors that belong to the set-valued mapping at any point in the set that serves as the argument of the set-valued mapping. The notation “ $\overline{\text{co}}F((x + \delta\mathbb{B}) \cap C)$ ” indicates the closed, convex hull of the set $\{f \in \mathbb{R}^n : f \in F(z), z \in (x + \delta\mathbb{B}) \cap C\}$. Note that $(C_0, F_0, D_0, G_0) = (C, F, D, G)$. More generally, the components of (C, F, D, G) are contained in $(C_{\delta}, F_{\delta}, D_{\delta}, G_{\delta})$. The inflation data in (2) satisfy the regularity properties of Assumption 1 when (C, F, D, G) do.

Proposition 3 *If the data (C, F, D, G) satisfy Assumption 1 then, for each $\delta > 0$, the inflated data $(C_\delta, F_\delta, D_\delta, G_\delta)$ satisfy Assumption 1.*

From the point of view of asymptotic stability, the behavior of solutions to $(C_\delta, F_\delta, D_\delta, G_\delta)$ for $\delta > 0$ small is not too different from those of (C, F, D, G) .

Theorem 5 *Under Assumption 1, if $\mathcal{A}$ is asymptotically stable with basin of attraction $\mathcal{B}_{\mathcal{A}}$ for the hybrid system with data (C, F, D, G) , then for each $\varepsilon > 0$ and each compact set K satisfying $K \subset \mathcal{B}_{\mathcal{A}}$, there exist $\delta > 0$ and a compact set $\mathcal{A}_\delta \subset \mathcal{A} + \varepsilon\mathbb{B}$ that is asymptotically stable with $K \subset \mathcal{B}_{\mathcal{A}_\delta}$ for $(C_\delta, F_\delta, D_\delta, G_\delta)$.*

The robustness result of Theorem 5 has several consequences beyond the observations in the preceding examples. One of the consequences is the following reduction principle.

Theorem 6 *Under Assumption 1, if $\mathcal{A}_1$ is asymptotically stable with basin of attraction $\mathcal{B}_{\mathcal{A}_1}$ for the hybrid system with data (C, F, D, G) and the compact set $\mathcal{A}_2 \subset \mathcal{A}_1$ is globally asymptotically stable for the hybrid system with data $(C \cap \mathcal{A}_1, F, C \cap \mathcal{A}_2, G)$, then the compact set $\mathcal{A}_2$ is asymptotically stable with basin of attraction $\mathcal{B}_{\mathcal{A}_1}$ for the hybrid system with data (C, F, D, G) .*

Lyapunov Functions

Arguably the most common method for establishing asymptotic stability is known as *Lyapunov's method* and uses a Lyapunov function. A function $V : \mathbb{R}^n \rightarrow \mathbb{R}_{\geq 0}$ is a *Lyapunov function candidate* for (1) if it is continuously differentiable on an open neighborhood of the flow set C , it is defined for all $x \in C \cup D \cup G(D)$ (dom V denotes the set of points where it is defined), and it is continuous on its domain. Some of these conditions can be relaxed but are imposed in this entry to keep the discussion simple. Given a compact set $\mathcal{A}$ and an open set O satisfying $\mathcal{A} \subset O \subset \mathbb{R}^n$, a Lyapunov function candidate for (1) is called a *Lyapunov function* for $(\mathcal{A}, O)$ if:

(L1) For $x \in (C \cup D \cup G(D)) \cap O$, $V(x) = 0$ if and only if $x \in \mathcal{A}$.

(L2) For each $x \in C \cap O$ and $f \in F(x)$, $\langle \nabla V(x), f \rangle \leq 0$.

(L3) For each $x \in D \cap O$ and $g \in G(x)$, $V(g) - V(x) \leq 0$.

A Lyapunov function for $(\mathcal{A}, O)$ is called a *proper Lyapunov function* for $(\mathcal{A}, O)$ if, in addition,

(L4) $\lim_{i \rightarrow \infty} V(x_i) = \infty$ when the sequence $\{x_i\}_{i=0}^\infty$, satisfying $x_i \in (C \cup D \cup G(D)) \cap O$ for all $i \in \mathbb{Z}_{\geq 0}$, is unbounded or approaches the boundary of O .

The next result does not use Assumption 1, though the rest of the results in this entry do.

Theorem 7 *Let $\mathcal{A} \subset O \subset \mathbb{R}^n$ with $\mathcal{A}$ compact and O open. If there exists a Lyapunov function for $(\mathcal{A}, O)$, then $\mathcal{A}$ is Lyapunov stable for (1). If there exists a proper Lyapunov function for $(\mathcal{A}, O)$ then $\mathcal{A}$ is also Lagrange stable with respect to O for (1).*

We can also conclude asymptotic stability from a Lyapunov function when it is known that there are no complete solutions along which the Lyapunov function is equal to a positive constant.

Theorem 8 *Let $\mathcal{A} \subset O \subset \mathbb{R}^n$ with $\mathcal{A}$ compact and O open. Under Assumption 1, if there exists a Lyapunov function for $(\mathcal{A}, O)$ and there is no solution x of (1) starting in $O \setminus \mathcal{A}$ that has an unbounded time domain and satisfies $V(x(t, j)) = V(x(0, 0))$ for all $(t, j) \in \text{dom } x$, then $\mathcal{A}$ is uniformly asymptotically stable for (1). If the Lyapunov function is a proper Lyapunov function for $(\mathcal{A}, O)$, then the basin of attraction for $\mathcal{A}$ contains O .*

The simplest way to rule out solutions that keep a Lyapunov function equal to a positive constant is by finding a (proper) *strict Lyapunov function* for $(\mathcal{A}, O)$, which is a (proper) Lyapunov function for $(\mathcal{A}, O)$ that also satisfies:

(L2') For each $x \in (C \cap O) \setminus \mathcal{A}$ and $f \in F(x)$, $\langle \nabla V(x), f \rangle < 0$.

(L3') For each $x \in (D \cap O) \setminus \mathcal{A}$ and $g \in G(x)$,
 $V(g) - V(x) < 0$.

Theorem 9 Let $\mathcal{A} \subset O \subset \mathbb{R}^n$ with $\mathcal{A}$ compact and O open. Under Assumption 1, if there exists a strict Lyapunov function for $(\mathcal{A}, O)$, then $\mathcal{A}$ is uniformly asymptotically stable for (1). If there exists a proper strict Lyapunov function for $(\mathcal{A}, O)$, then $\mathcal{A}$ is uniformly asymptotically stable for (1) with basin of attraction containing O .

While a strict Lyapunov function can be difficult to find, and this fact has motivated other more sophisticated stability analysis tools that have appeared in the literature, it is reassuring to know that whenever $\mathcal{A}$ is compact and asymptotically stable, there exists a proper strict Lyapunov function for $(\mathcal{A}, \mathcal{B}_{\mathcal{A}})$.

Theorem 10 Under Assumption 1, if the compact set $\mathcal{A}$ is asymptotically stable for (1), then there exists a proper strict Lyapunov function for $(\mathcal{A}, \mathcal{B}_{\mathcal{A}})$. More specifically, for each $\lambda > 0$ there exists a smooth function V with $\text{dom } V = \mathcal{B}_{\mathcal{A}}$ that $V(x) = 0$ if and only if $x \in \mathcal{A}$, $\lim_{i \rightarrow \infty} V(x_i) = \infty$ when the sequence $\{x_i\}_{i=0}^{\infty}$, satisfying $x_i \in \mathcal{B}_{\mathcal{A}}$ for all $i \in \mathbb{Z}_{\geq 0}$, is unbounded or tends to the boundary of $\mathcal{B}_{\mathcal{A}}$, and such that:

1. For all $x \in C \cap \mathcal{B}_{\mathcal{A}}$ and $f \in F(x)$,
 $\langle \nabla V(x), f \rangle \leq -\lambda V(x)$.
2. For all $x \in D \cap \mathcal{B}_{\mathcal{A}}$ and $g \in G(x)$, $V(g) \leq \exp(-\lambda)V(x)$.

Summary and Future Directions

Under Assumption 1, stability theory for hybrid dynamical systems is very similar to stability theory for differential equations or difference equations with continuous right-hand sides. In particular, Lyapunov functions are a very common analysis tool for hybrid dynamical systems, though a Lyapunov function can be difficult to find in the same way that they are challenging to find for classical systems. With stability theory for hybrid dynamical systems firmly in place,

future research is expected to exploit this theory more fully for the development of control algorithms with new capabilities.

Abstract

The notion of stability allows to study the qualitative behavior of dynamical systems. In particular it allows to study the behavior of trajectories close to an equilibrium point or to a motion. The notion of stability that we discuss has been introduced in 1882 by the Russian mathematician A.M. Lyapunov in his doctoral thesis; hence it is often referred to as Lyapunov stability. In this article we discuss and characterize Lyapunov stability for linear systems.

Keywords

Linear systems · Equilibrium point · Motion · Stability · Eigenvalues

Introduction

Consider a linear, time-invariant, finite-dimensional system, i.e., a system described by equations of the form

$$\begin{aligned}\sigma x &= Ax + Bu, \\ y &= Cx + Du,\end{aligned}\tag{1}$$

with $x(t) \in \mathbb{R}^n$, $u(t) \in \mathbb{R}^m$, $y(t) \in \mathbb{R}^p$, $t \in T \subset \mathbb{R}$, and $A \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$, $C \in \mathbb{R}^{p \times n}$, and $D \in \mathbb{R}^{p \times m}$ constant matrices. In equation (1) $\sigma x(t)$ stands for $\dot{x}(t)$ if the system is continuous-time and for $x(t+1)$ if the system is discrete-time. Since the system is time-invariant,

it is assumed, without loss of generality, that all signals are defined for $t \geq 0$, that is, if the system is continuous-time then $T = \mathbb{R}^+$, i.e., the set of nonnegative real numbers, whereas if the system is discrete-time then $T = \mathbb{Z}^+$, i.e., the set of nonnegative integers. For ease of notation, the argument “ t ” is dropped whenever this does not cause confusion and we use the notation $t \geq 0$ to denote either $\mathbb{R}^+$ or $\mathbb{Z}^+$. Finally, we use either $x(t, x(0), u)$ or $x(t)$ to denote the solution of the first of equations (1) at a given time $t \geq 0$, with the initial condition $x(0)$ and the input signal u . The former is used when it is important to keep track of the initial state and external input u , whereas the latter is used whenever there is not such a need.

Definition 1 (Equilibrium) Consider the system (1). Assume the input u is constant, i.e., $u(t) = u_0$ for all $t \geq 0$ and for some constant u_0 . A state x_e is an equilibrium of the system associated to the input u_0 if $x_e = x(t, x_e, u_0)$, for all $t \geq 0$.

Proposition 1 (Equilibria of linear systems) Consider the system (1) and assume $u(t) = u_0$, for all t , where u_0 is a constant vector. Then the following holds

- If $u_0 = 0$ then the origin is an equilibrium.
- For continuous-time systems, if A is invertible, for any u_0 there is a unique equilibrium $x_e = -A^{-1}Bu_0$. If A is not invertible, the system has either infinitely many equilibria or it has no equilibria.
- For discrete-time systems, if $I - A$ is invertible, for any u_0 there is a unique equilibrium $x_e = (I - A)^{-1}Bu_0$. If $I - A$ is not invertible the system has either infinitely many equilibria or it has no equilibria.

Proposition 2 Consider the continuous-time, time-invariant, linear system described by the equations

$$\begin{aligned}\dot{x} &= Ax + Bu, \\ y &= Cx + Du,\end{aligned}$$

and the initial condition $x(0) = x_0$. Then, for all $t \geq 0$,

$$x(t) = e^{At}x_0 + \int_0^t e^{A(t-\tau)}Bu(\tau)d\tau \quad (2)$$

and

$$y(t) = Ce^{At}x_0 + \int_0^t Ce^{A(t-\tau)}Bu(\tau)d\tau + Du(t). \quad (3)$$

Proposition 3 Consider the discrete-time, time-invariant, linear system described by the equations (to simplify notation we use $x^+(t)$ to denote $x(t+1)$ and we drop the argument t)

$$\begin{aligned} x^+ &= Ax + Bu, \\ y &= Cx + Du, \end{aligned}$$

and the initial condition $x(0) = x_0$. Then, for all $t \geq 0$,

$$x(t) = A^t x_0 + \sum_{i=0}^{t-1} A^{t-1-i} Bu(i) \quad (4)$$

and

$$y(t) = CA^t x_0 + \sum_{i=0}^{t-1} CA^{t-1-i} Bu(i) + Du(t). \quad (5)$$

Definitions

In this section we provide some notions and definitions which are applicable to general dynamical systems, despite being formulated with reference to the system (1).

Definition 2 (Lyapunov stability) Consider the system (1) with $u(t) = u_0$, for all $t \geq 0$ and for some constant u_0 . Let x_e be an equilibrium point. The equilibrium is stable (in the sense of Lyapunov) if for every $\epsilon > 0$ there exists a $\delta = \delta(\epsilon) > 0$ such that (the notation $\|\cdot\|$ denotes the Euclidean norm in $\mathbb{R}^n$) $\|x(0) - x_e\| < \delta$ implies $\|x(t) - x_e\| < \epsilon$, for all $t \geq 0$.

In stability theory the quantity $x(0) - x_e$ is called initial perturbation, and $x(t)$ is called perturbed evolution. Therefore, the definition

of stability can be interpreted as follows. An equilibrium point x_e is stable if however we select a *tolerable* deviation ϵ , there exists a (possibly small) neighborhood of the equilibrium x_e such that all initial conditions in this neighborhood yield trajectories which are within the *tolerable* deviation.

The property of stability dictates a condition on the evolution of the system for all $t \geq 0$. Note, however, that in the definition of stability we have not requested that the perturbed evolution converge asymptotically, that is, for $t \rightarrow \infty$, to x_e . This convergence property is very important in applications, as it allows to characterize the situation in which not only the perturbed evolution remains close to the unperturbed evolution, but it also converges to the initial (unperturbed) evolution. To capture this property we introduce a new definition.

Definition 3 (Asymptotic stability) Consider the system (1) with $u(t) = u_0$, for all $t \geq 0$ and for some constant u_0 . Let x_e be an equilibrium point. The equilibrium is asymptotically stable if it is stable and if there exists a constant $\delta_a > 0$ such that $\|x(0) - x_e\| < \delta_a$ implies $\lim_{t \rightarrow \infty} \|x(t) - x_e\| = 0$.

In summary, an equilibrium point is asymptotically stable if it is stable and, whenever the initial perturbation is inside a certain neighborhood of x_e , the perturbed evolution converges, asymptotically, to the equilibrium point, which is thus said to be attractive. From a physical point of view this means that all sufficiently small initial perturbations give rise to effects which can be a priori bounded (stability) and which vanish asymptotically (attractivity).

It is important to highlight that, in general, attractivity does not imply stability: it is possible to have an equilibrium of a system which is not stable (i.e., it is unstable), yet for all initial perturbations the perturbed evolution converges to the equilibrium. This however is not the case for linear systems, as discussed in the section “[Stability of Linear Systems](#)”. We conclude the section with two simple examples illustrating the notions that have been introduced.

Example 1 Consider the discrete-time system $x^+ = -x$, with $x(t) \in \mathbb{R}$. This system has a unique equilibrium at $x_e = 0$. Note that for any initial condition $x_0 \in \mathbb{R}$ one has

$$x(2t - 1) = -x_0, \quad x(2t) = x_0,$$

for all $t \geq 1$ and integer. This implies that the equilibrium is stable, but not attractive.

Example 2 Consider the continuous-time system

$$\dot{x}_1 = \omega x_2, \quad \dot{x}_2 = -\omega x_1,$$

with ω a positive constant. The system has a unique equilibrium at $x_e = 0$. This equilibrium is stable, but not attractive. To see this note that, along the trajectories of the system, $x_1 \dot{x}_1 + x_2 \dot{x}_2 = 0$, and this implies that, along the trajectories of the system, $x_1^2(t) + x_2^2(t)$ is constant, i.e., $x_1^2(t) + x_2^2(t) = x_1^2(0) + x_2^2(0)$. Therefore the state of the system remains on the circle centered at the origin and with radius $\sqrt{x_1^2(0) + x_2^2(0)}$ for all $t \geq 0$: the condition for stability holds with $\delta(\epsilon) = \epsilon$.

Definition 4 (Global asymptotic stability)

Consider the system (1) with $u(t) = u_0$, for all $t \geq 0$ and for some constant u_0 . Let x_e be an equilibrium point. The equilibrium is globally asymptotically stable if it is stable and if, for all $x(0)$, $\lim_{t \rightarrow \infty} \|x(t) - x_e\| = 0$.

The property of (global) asymptotic stability can be strengthened imposing conditions on the convergence speed of $\|x(t) - x_e\|$.

Definition 5 (Exponential stability)

Consider the system (1) with $u(t) = u_0$, for all $t \geq 0$ and for some constant u_0 . Let x_e be an equilibrium point. The equilibrium is exponentially stable if there exists $\lambda > 0$, in the case of continuous-time systems, and $0 < \lambda < 1$, in the case of discrete-time systems, such that for all $\epsilon > 0$ there exists a $\delta = \delta(\epsilon) > 0$ such that $\|x(0) - x_e\| < \delta$ implies $\|x(t) - x_e\| < \epsilon e^{-\lambda t}$, in the case of continuous-time systems, and $\|x(t) - x_e\| < \epsilon \lambda^t$, in the case of discrete-time systems, for all $t \geq 0$.

Definition 6 (Stability of motion) Consider the system (1). Let

$$\mathcal{M} = \{(t, x(t)) \in T \times \mathbb{R}^n\},$$

with $x(t) = x(t, x_0, u)$, for given x_0 and u , and $T = \mathbb{R}^+$, in the case of continuous-time systems, and $T = \mathbb{Z}^+$, in the case of discrete-time systems, be a motion. The motion is stable if for every $\epsilon > 0$ there exists a $\delta = \delta(\epsilon) > 0$ such that $\|x(0) - x_0\| < \delta$ implies

$$\|x(t, x(0), u) - x(t, x_0, u)\| < \epsilon, \quad (6)$$

for all $t \geq 0$.

The notion of stability of a motion is substantially the same as the notion of stability of an equilibrium. The important issue is that the time parametrization is important, i.e., a motion is stable if, for small initial perturbations, the perturbed evolution is close, for any fixed $t \geq 0$, to the unperturbed evolution. This does not mean that if the perturbed and unperturbed trajectories are close, then the motion is stable: in fact the trajectories may be close but may be followed with different timing, which means that for some $t \geq 0$ condition (6) may be violated.

Stability of Linear Systems

The notion of stability relies on the knowledge of the trajectories of the system. As a result, even if this notion is very elegant, and useful in applications, it is in general hard to assess stability of an equilibrium or of a motion. There are, however, classes of systems for which it is possible to give stability conditions without relying upon the knowledge of the trajectories. Linear systems belong to one such class. In this section we study the stability properties of linear systems and we show that, because of the linear structure, it is possible to assess the properties of stability and attractivity in a simple way. To begin with, we recall some properties of linear systems.

Proposition 4 Consider a linear, time-invariant system. (Asymptotic) stability of one motion

implies (asymptotic) stability of all motions. In particular, (asymptotic) stability of any motion implies and is implied by (asymptotic) stability of the equilibrium $x_e = 0$.

The above statement, together with the result in Proposition 1, implies the following important properties.

Proposition 5 *If the origin of a linear system is asymptotically stable then the origin is the only equilibrium of the system for $u = 0$. Moreover, asymptotic stability of the zero equilibrium is always global. Finally, asymptotic stability implies exponential stability.*

The above discussion shows that the stability properties of a motion (e.g., an equilibrium) of a linear system are inherited by all motions of the system. Moreover, for linear systems, local properties are always global properties. This means that, with some abuse of terminology, we can refer the stability properties to the linear system, for example we say that a linear system is stable to mean that all its motions are stable. Stability properties of a linear, time-invariant, system are therefore properties of the *free* evolution of its state: for this class of systems it is possible to obtain simple stability tests.

Proposition 6 *A linear, time-invariant, system is stable if and only if $\|e^{At}\| \leq k$, for continuous-time systems, or $\|A^t\| \leq k$, for discrete-time systems, for all $t \geq 0$ and for some $k > 0$. It is asymptotically stable if and only if $\lim_{t \rightarrow \infty} e^{At} = 0$, for continuous-time systems, or $\lim_{t \rightarrow \infty} A^t = 0$, for discrete-time systems.*

Proposition 7 *The equilibrium $x_e = 0$ of a linear, time-invariant, system is stable if and only if the following conditions hold*

- *In the case of continuous-time systems, the eigenvalues of A with geometric multiplicity equal to one have nonpositive real part, and the eigenvalues of A with geometric multiplicity larger than one have negative real part.*
- *In the case of discrete-time systems, the eigenvalues of A with geometric multiplicity equal to one have modulo not larger than one, and*

the eigenvalues of A with geometric multiplicity larger than one have modulo smaller than one.

Remark 1 To define the geometric multiplicity of an eigenvalue, we need to recall a few facts. Consider a matrix $A \in \mathbb{R}^{n \times n}$ and a polynomial $p(\lambda)$. The polynomial $p(\lambda)$ is a zeroing polynomial for A if $p(A) = 0$. Note that, by Cayley-Hamilton Theorem, the characteristic polynomial of A is a zeroing polynomial for A . Among all zeroing polynomials, there is a unique monic polynomial $p_M(\lambda)$ with smallest degree. This polynomial is called the minimal polynomial of A . Note that the minimal polynomial of A is a divisor of the characteristic polynomial of A . If A has $r \leq n$ distinct eigenvalues $\lambda_1, \dots, \lambda_r$ then

$$p_M(\lambda) = (\lambda - \lambda_1)^{m_1} (\lambda - \lambda_2)^{m_2} \dots (\lambda - \lambda_r)^{m_r},$$

where the number m_i denotes, by definition, the geometric multiplicity of λ_i , for $i = 1, \dots, r$. This means that the geometric multiplicity of λ_i equals the multiplicity of λ_i as a root of $p_M(\lambda)$. Recall, finally, that the multiplicity of λ_i as a root of the characteristic polynomial is called algebraic multiplicity.

Proof. Let $\lambda_1, \lambda_2, \dots, \lambda_r$, with $r \geq 1$, be the distinct eigenvalues of A , i.e., the distinct roots of the characteristic polynomial of A . Then

$$e^{At} = \sum_{i=1}^r \sum_{k=1}^{m_i} R_{ik} \frac{t^{k-1}}{(k-1)!} e^{\lambda_i t},$$

for some matrices R_{ik} , where m_i is the geometric multiplicity of the eigenvalue λ_i . This matrix is bounded if and only if the conditions in the statement hold. Similarly,

$$A^t = \sum_{i=1}^r \sum_{k=1}^{m_i} R_{ik} \frac{t^{k-1}}{(k-1)!} \lambda_i^{t-k+1},$$

for some matrices R_{ik} , and this is bounded if and only if the conditions in the statement hold. $\triangleleft$

Proposition 8 *The equilibrium $x_e = 0$ of a linear, time-invariant, system is asymptotically stable if and only if the following conditions hold*

- *In the case of continuous-time systems, the eigenvalues of A have negative real part.*
- *In the case of discrete-time systems, the eigenvalues of A have modulo smaller than one.*

Proof. The proof is similar to the one of the previous proposition, once it is noted that, for the considered class of systems, and as stated in Proposition 6, asymptotic stability implies and is implied by boundedness and convergence of e^{At} or A^t . $\triangleleft$

Remark 2 For linear, time-varying, systems, i.e., systems described by equations of the form

$$\begin{aligned}\dot{x} &= A(t)x + B(t)u, \\ y &= C(t)x + D(t)u,\end{aligned}$$

it is possible to provide stability conditions in the spirit of the boundedness and convergence conditions in Proposition 6. These require the definition of a matrix, the so-called state transition matrix, which describes the free evolution of the state of the system. It is, however, not possible to provide conditions in terms of eigenvalues of the matrix $A(t)$, for each t , similar to the conditions in Propositions 7 and 8.

We conclude this discussion with an alternative characterization of asymptotic stability in terms of linear matrix inequalities.

Proposition 9 *The equilibrium $x_e = 0$ of a linear, time-invariant, system is asymptotically stable if and only if the following conditions hold*

- *In the case of continuous-time systems, there exists a positive definite matrix $P = P'$ such that $A'P + PA < 0$.*

- *In the case of discrete-time systems, there exists a positive definite matrix $P = P'$ such that $A'PA - P < 0$.*

Remark 3 P' denotes the transpose of the matrix P . A square and symmetric matrix $P \in \mathbb{R}^{n \times n}$ is positive definite, denoted $P > 0$, if $v'Pv > 0$, for all nonzero vectors $v \in \mathbb{R}^n$. A matrix P is negative definite, denoted $P < 0$, if $-P > 0$.

To complete our discussion we stress that stability properties are invariant with respect to changes in coordinates in the state space.

Corollary 1 *Consider a linear, time-invariant, system and assume it is (asymptotically) stable. Then any representation obtained by means of a change of coordinates of the form $x(t) = L\hat{x}(t)$, with L constant and invertible, is (asymptotically) stable.*

Proof. The proof is based on the observation that the change of coordinates transforms the matrix A into $\tilde{A} = L^{-1}AL$ and that the matrices A and $\tilde{A}$ are similar, that is, they have the same characteristic and minimal polynomials. $\triangleleft$

Summary and Future Directions

The property of Lyapunov stability is instrumental to characterize the qualitative behavior of dynamical systems. For linear, time-invariant, systems this property can be studied on the basis of the location, and multiplicity, of the eigenvalues of the matrix A . The property of Lyapunov stability can be studied for more general classes of systems, including nonlinear systems, distributed parameter systems, and hybrid systems, to which the basic definitions given in this article apply.

State Estimation for Batch Processes

Wolfgang Mauntz
Fakultät Bio- und Chemieingenieurwesen,
Technische Universität Dortmund, Dortmund,
Germany

Abstract

The information about certain safety or quality parameters during a batch process is valuable for a variety of reasons. In case a direct measurement is too expensive, too slow, or nonexisting, a state estimator estimating the desired

quantities based on a model and various other measurements may be a good alternative. The most prominent method is calorimetry, where the heat of reaction is measured. This article gives an overview of different alternatives that support a safe and successful batch operation.

Keywords

Observer · Soft sensor · State estimator · Calorimetry

Introduction

Continuous processes are used to produce a product at a constant rate. They are designed to operate at constant conditions, i.e., the state of the process (conversion, temperatures, pressures, concentrations, etc.) does not vary. In contrast, (semi-) batch processes execute a recipe which means that they are typically operated within a wide range of states. The state of the (semi-batch) process should constantly be monitored. This information is useful for several purposes:

- *Process safety*: abnormal process states such as the accumulation of hazardous substances or reactive materials may lead to dangerous situations such as runaway reactions. The earlier an abnormal state is detected, the better it can be corrected, and the higher is the probability that loss can be avoided.
- *Quality*: if the batch is not operated along the standard trajectory, off-spec product may result which in turn results in extra effort and/or second grade product if this is discovered in time and in a customer complaint if not discovered before delivery.
- *Profit*: the better the state is known, the less conservative the underlying control scheme needs to be, and the more the process can be pushed to its limits. This may lead to a higher throughput, less by-products, or less energy consumption. Advanced control schemes which are typically applied for this purpose require knowledge of the state of the process.

The literature offers a wide range of ways to monitor a batch process. In some processes, the observation of simple measurements like temperatures, pressures, and the time that a process step takes for execution is sufficient to guarantee for safe standard product in minimum time. Examples include some melt polymerizations.

However, as soon as the process is more complex, more information than just temperatures and pressures is required to monitor the process to meet the goals mentioned above. It may be sufficient to measure other easy-to-measure properties like conductivities, flowrates, pH values, sound velocities, attenuations, etc.; however in many cases these measurements do not give the complete state of the system. Properties like complex gas phase compositions cannot be measured this way. This might require the installation of more sophisticated measurements, e.g., NIR spectroscopy, online gas chromatography, Raman spectroscopy, or ion mobility spectroscopy. These measurements require significant effort in terms of installation cost and maintenance. In other situations, no online measurement may be available at all. These cases include the measurement of the distribution of the molecular weight in a polymer melt.

In these cases, where direct online measurements are either too expensive or not available at all, several methods are available to obtain information on the status of the batch Estimation in Systems and Control.

- *Statistical Methods*

Experiences from historical batches are used in a statistical way to predict whether a batch runs normally. This can, e.g., be accomplished by defining a golden batch and a corresponding corridor around these trajectories. More sophisticated methods use principal component analysis (PCA) or partial least squares (PLS) to get a hint at abnormal situations. These methods are even capable of pointing at the origin of a possible problem. They are restricted to problem detection and typically cannot be used for control purposes.

- *Model-Based State Estimation*

The state of the system (temperatures, pressures, concentrations, etc.) is estimated online which allows for problem detection as well as control applications. This method will be described in more detail in section [Model-Based State Estimation](#)

General reviews of state estimation techniques can be found in Besancon (2007) and Schei (2008), and a review of industrial applications is, e.g., given in Fortuna et al. (2007).

Model-Based State Estimation

The basic idea of a state estimator (which is frequently also called *observer* or *soft sensor*) is to run a mathematical model of the process in parallel to the process itself, to compare the available measurements to the values which are predicted by the model, and to correct the estimated state by a suitable function of the observed error, usually an additive correction term that depends on the error. For a state estimator to converge to the true state, the considered system needs to be observable. For details see ► [“Controllability and Observability”](#). The scheme of a state estimator is sketched in Fig. 1. The real system processes the input $\mathbf{u}$ to give the system state $\mathbf{x}$ which is affected by the system noise ξ . The measurements $\mathbf{y}$ are perturbed by the measurement noise φ . The model predicts a system state $\hat{\mathbf{x}}$ and a measurement $\hat{\mathbf{y}}$. The difference between the measured value $\mathbf{y}$ and predicted value $\hat{\mathbf{y}}$ is then fed back to correct the estimated state.

For **linear systems**, the most commonly used state estimators are the *Luenberger Observer* and the *Kalman filter* ► [“Kalman Filters”](#). Both multiply the prediction error ($\mathbf{y} - \hat{\mathbf{y}}$) by a weighting matrix $\mathbf{K}$ to update the estimated state $\hat{\mathbf{x}}$:

$$\dot{\hat{\mathbf{x}}} = \mathbf{A}\hat{\mathbf{x}} + \mathbf{B}\mathbf{u} + \mathbf{K}(\mathbf{y} - \hat{\mathbf{y}})$$

The two techniques use different approaches for determining the matrix $\mathbf{K}$:

Luenberger Observer The basic assumption is that the deviation $\mathbf{e}(t)$ between $\mathbf{x}$ and $\hat{\mathbf{x}}$ is due

State Estimation for Batch Processes, Fig. 1

Principle of a state estimator

to wrong initial values $\hat{\mathbf{x}}_0$. $\mathbf{K}$ is computed by choosing the desired speed of convergence of the error

$$\begin{aligned}\dot{\mathbf{e}}(t) &= \dot{\mathbf{x}}(t) - \dot{\hat{\mathbf{x}}}(t) \\ &= (\mathbf{A} - \mathbf{K}\mathbf{C}) \mathbf{e}(t).\end{aligned}$$

to zero. This is done by placing the eigenvalues of the matrix $(\mathbf{A} - \mathbf{K}\mathbf{C})$ in the left half plane.

Kalman filter The basic assumption is that the error $\mathbf{e}(t)$ is caused by white noise in the system ξ as well as in the measurement φ . The idea is to minimize the expectation of the quadratic error

$$\min_{\hat{\mathbf{x}}} E \left((\hat{\mathbf{x}}(t) - \mathbf{x}(t))^T (\hat{\mathbf{x}}(t) - \mathbf{x}(t)) \right).$$

$\mathbf{K}$ is computed from the noise covariance matrices and the system dynamics and varies with time.

The tuning of the state estimators is not trivial. The larger the absolute value of the eigenvalues in the Luenberger approach, the faster the error will converge to zero, but the more prone the state estimator will be to measurement noise. A similar trade-off exists for the Kalman filter where the covariance matrices of the noise terms ξ and φ

and the covariance of the initial state ξ_0 need to be defined.

For **nonlinear systems**, a variety of approaches is available. The most frequently used estimators are based on using the nonlinear model for the prediction of the state, and linearizations of the system dynamics are used to update the matrix $\mathbf{K}$. The *extended Kalman filter (EKF)* ▶ “[Extended Kalman Filters](#)” and the *extended Luenberger Observer (ELO)* are representatives of this class of approaches. The EKF is most widely used. Extensions are the *constrained EKF* and the *unscented EKF*.

As examples are known where the EKF fails due the nonlinearity of the system, methods based on ideas other than the linearization of system dynamics have been developed. These methods include the *moving horizon estimator (MHE)* ▶ “[Moving Horizon Estimation](#)” and the *particle filter*. Because of the increasing capabilities of modern computers and significant improvements in dynamic optimization algorithms, the MHE is a very promising alternative. The idea of the method is to minimize the sum of the squared errors of the system noise ξ_l , the measurement noise φ_l , and the error of the initial state ξ_{k-N} which are weighted by weighing matrices $\mathbf{P}_k$, $\mathbf{Q}$, and $\mathbf{R}$ over a pre-defined horizon of past sampling steps $k - N, \dots, k$

$$\min_{\xi_i, \varphi_j} \xi_{k-N}^T \mathbf{P}_k^{-1} \xi_{k-N} + \sum_{l=k-N+1}^{k-1} \xi_l^T \mathbf{Q}^{-1} \xi_l + \sum_{l=k-N+1}^k \varphi_l^T \mathbf{R}^{-1} \varphi_l$$

s.t. the system model and the measurement equations are satisfied

and further inequality constraints (e.g., physical limits of variables) hold.

The possibility to define constraints on the estimated states, e.g., that concentrations must be nonnegative, is an important advantage of the MHE approach. If the horizon is reduced to one single measurement, the constrained extended Kalman filter results which combines the simplicity of the EKF with the possibility to include constraints on the estimated states. Efficient implementations of the MHE have led to the method being capable of estimating the state of rather large systems in real time (Diehl et al. 2006; Küpper and Engell 2007).

Calorimetry

Temperature measurements are probably the cheapest available measurements in chemical processes, and most plants are typically well equipped with temperature sensors. To exploit temperature measurements, e.g., for the observation of exothermic or endothermic reactions, heat balances are set up and solved for the heat of reaction which then enables the computation of the reaction rate. This is typically referred to as **calorimetry**. Reviews are given, e.g., in Hergeth (2006), McKenna et al. (2000), and Landau (1996). For a jacketed reactor, the heat balance around a semi-batch reactor typically reads (see also Fig. 2)

$$C_{P,R} \frac{dT_R}{dt} = \dot{Q}_R + kA(T_J - T_R) + \sum_i \dot{m}_{F,i} c_{p,Fi} (T_{F,i} - T_R), \quad (1)$$

where $\dot{Q}_R$ represents the heat of reaction, kA is the overall heat transfer coefficient between the reactor content and the jacket, T_R is the reactor temperature, T_J is the jacket temperature, T_F is the feed temperature, $C_{P,R}$ is the overall heat capacity of the reactor, and the last term on the right side is the enthalpy added by the feed to the reactor. If kA is known, $\dot{Q}_R$ can directly be computed as all other quantities in Eq. (1) are known or measured. This is referred to as *heat flow calorimetry*.

In industrial practice, kA usually is not known and varies over time due to changes of the filling level, changes of the viscosity of the reaction mixture and fouling. Then other heat balances and measurements can be added to enable a direct computation or estimation of kA . Typically, the jacket heat balance is chosen

$$C_{P,J} \frac{dT_J}{dt} = kA(T_R - T_J) + kA_{\text{jack}}(T_{\text{env}} - T_J) + \dot{m}_J c_{p,J} (T_{J,\text{in}} - T_J). \quad (2)$$

If necessary, also other phenomena like direct heat losses from the reactor content to the environment or the influence of the reactor lid can be taken into account by adding additional terms or additional heat balances. This method is called *heat balance calorimetry*.

In order to compute $\dot{Q}_R$ and kA from Eqs. (1) and (2), two different approaches can be used:

1. Equations (1) and (2) are solved to give

$$\hat{kA} = \frac{C_{P,J} \frac{dT_J}{dt} - kA_{\text{jack}}(T_{\text{env}} - T_J) - \dot{m}_J c_{p,J} (T_{J,\text{in}} - T_J)}{T_R - T_J} \quad (3a)$$

$$\hat{\dot{Q}}_R = C_{P,R} \frac{dT_R}{dt} - kA(T_J - T_R) - \sum_i \dot{m}_{F,i} c_{p,Fi} (T_{F,i} - T_R). \quad (3b)$$

In this approach, the derivatives need to be computed from the measurements which introduce noise in the evaluation and require a filtering either of the derivatives or of the estimates.

2. Equations (1) and (2) are implemented in a nonlinear state estimator. To estimate the unknown quantities $\hat{kA}$ and $\hat{\dot{Q}}_R$ by this approach, additional assumptions about their dynamics must be made. A common approach

State Estimation for Batch Processes, Fig. 2

The reactor and its jacket as considered for calorimetry

is to add the so-called dummy derivatives

$$\frac{d \hat{Q}_R}{dt} = 0$$

$$\frac{d \hat{k}A}{dt} = 0.$$

The tuning of calorimetric estimation schemes has been discussed in the literature, but for each case, tests in simulation runs using recorded batch data should be performed.

Experimental results of the application of the direct solution Eq. (3) and an EKF for the estimation of $\dot{Q}_R$ and kA are shown in Fig. 3. A laboratory scale 10 l metal reactor was filled with water. Cold water was injected into the reactor to simulate the feed of reactants. The reactor is equipped with a heating rod by which different values of $\dot{Q}_R$ could be simulated. Figure 3a shows the measured temperatures and the feed stream; Fig. 3b shows the estimates. The dotted line displays the measured power uptake, the thin, black line represents the estimates from the evaluation of Eq. (3), and the gray line shows the results obtained with an EKF. The EKF was tuned slightly more aggressively than the PT1 filter that was used to filter the

values of $\hat{Q}_R$ and $\hat{k}A$ that were obtained from Eqs. (3).

It can be seen that the quality of both evaluation methods is comparable. A difference in performance can be seen in the estimation of kA at the points in time where $T_R \approx T_J$. This is due to the denominator in Eq. (3a) which becomes ≈ 0 . At this point, kA is unobservable. The EKF estimates of kA are more smooth. This does not have an impact on the estimation of $\dot{Q}_R$ because the heat transfer from the jacket to the reactor is zero at this point. This behavior is of importance if $\hat{k}A$ is used in other algorithms, e.g., for control purposes.

A practical problem is the determination of the parameters of the system model. Especially the heat capacity of the reactor $C_{P,R}$ is difficult to determine as it is not clear how much impact the reactor material has. Also the heat capacities of intermediate products and mixtures with the raw materials and final products may not be known. That is why typically $C_{P,R}$ is considered a "free" parameter which is used to fit the estimates to measured data. If the adjustment of the available parameters is not sufficient to yield a satisfactory performance of the estimator, further extensions can be considered:

State Estimation for Batch Processes, Fig. 3 Illustration of the results of direct estimation (Eq. 3) and the use of an EKF. (a) Measured data. (b) Estimates from inverted equations (3) and EKF as well as measured $\hat{Q}_R$

State Estimation for Batch Processes, Fig. 4 Example experiment where TOC is applied. (a) Complete example. (b) Zoom of rectangle (A)

- If pressurized vessels are considered, the wall thickness may be considerable, and the heat accumulation may influence the results. In this case, the extension of the set of equations by an equation for the heat transfer through the wall may be considered (Saenz de Buruaga et al. 1997).
- If large-scale vessels are considered, the cooling fluid in the jacket may not be perfectly mixed, and a temperature gradient will be present. In many cases, cooling coils are welded on the outside surface of the reactor. In this case, the equation for the perfectly mixed jacket (Eq. 2) should be replaced by a model for a plug flow reactor (Krämer and Gesthuisen 2005).
- For large industrial reactors, the perfect mixing assumption of the reactor contents does

not necessarily hold true. Especially if polymerization reactions are considered, the reactor content may become rather viscous. A straightforward method to cope with this problem is a detailed computational fluid dynamics (CFD) simulation. However, due to the numerical complexity, this appears infeasible for online applications. A practical alternative is the placement of several temperature sensors and using a weighted average over their readings. A different approach is the usage of a multi-zonal model, the idea of which resembles the idea of a CFD model; however the number of zones (elements) is much smaller (Bezzo et al. 2004).

Heat balance calorimetry becomes inaccurate if the mass flow through the jacket is so large that

the temperature difference between the cooling stream entering the jacket and leaving the jacket ($T_{J,in} - T_J$) is in the order of magnitude of the measurement error. This mode of operation is typically used in laboratory scale reactors to avoid temperature gradients in the jacket. To estimate the states in such setups, a technique called *temperature oscillation calorimetry* (TOC) can be used. The idea is to add a small but well measurable sinusoidal signal to the typically constant setpoint of the reactor temperature T_R (see Fig. 4 for an example). The reaction of the jacket temperature to the oscillating reactor temperature can be used to compute kA , e.g., by estimating its amplitude δT_J (Tietze et al. 1996) or by adding an additional equation which describes the second derivative of the reactor temperature $\frac{d^2 T_R}{dt^2}$ to the set of heat balances (Mauntz et al. 2007).

Calorimetry estimates the total heat of the reactions in the reactor. It can be used to estimate the overall chemical conversion of a process. Due to its integral character, the heat of reaction of parallel and consecutive reactions cannot be estimated separately (Hergeth 2006). However, if models of the chemical kinetics are known and reliable, it is possible to couple this kinetic model with calorimetry and to observe the complete state of the reaction based on calorimetric estimates. This solution may however not be robust as slight errors in the kinetic model may lead to significant errors in the estimates of all concentrations. In order to build a more robust state estimator, additional measurements should be installed and integrated into the state estimator. For example, for reactions including a phase change from the gas phase to the liquid phase, a pressure measurement may be suitable. For some polymerization reactions, sound velocity and sound attenuation measurements can be valuable (Brandt et al. 2012). The additional measurement can be incorporated into the observation scheme by augmenting the measurement model $\mathbf{g}$ (see Fig. 1) by the corresponding measurement equation.

Summary

In this contribution, different methods that can be used to determine the states of (semi-) batch reactions have been described. State estimation is useful to reconcile measurement errors and whenever direct online measurements are either too expensive or not available at all.

Linear state estimation is a mature topic. However as chemical batch reactors in most cases have nonlinear dynamics, nonlinear methods should be applied. Extensions of linear state estimators based on linearizations of the system (e.g., the EKF) are the most widely used nonlinear state estimators. However examples are known where these estimators fail. Thus, other approaches, e.g., based on online optimization (MHE), have been developed. They deliver promising results in terms of observation quality and computational speed even for large-scale systems.

The most widespread application of state estimation techniques in batch processes is calorimetry which is suitable for significantly exothermic or endothermic reactions. The heat balances around the reactor contents and the jacket are set up and solved. The estimated heat of reaction is used to estimate the chemical conversion of the process. The method makes use of commonly installed temperature measurements in the reactor. Extensions to include other measurements have been discussed. Problems that typically occur in laboratory scale reactors can be overcome with the help of temperature oscillation calorimetry.

Statistical Process Control in Manufacturing

O. Arda Vanli¹ and Enrique Del Castillo²

¹Department of Industrial and Manufacturing Engineering, High Performance Materials Institute, Florida A&M University, Florida State University, Tallahassee, FL, USA

²Department of Industrial and Manufacturing Engineering, The Pennsylvania State University, University Park, PA, USA

Abstract

Statistical process control (SPC) has been successfully utilized for process monitoring and variation reduction in manufacturing applications. This entry aims to review some of the important monitoring methods. We discuss fundamental process monitoring topics including Shewhart's model, $\bar{X}$ and R control charts, EWMA and CUSUM charts for monitoring small process shifts, process monitoring for autocorrelated data, and integration of statistical and engineering (or automatic) control techniques. We also illustrate the application of SPC in the more recently emerging areas including monitoring profiles, surfaces, and point cloud data sets in manufacturing. The goal is to provide readers from control theory, mechanical engineering, and electrical engineering an expository overview of the key topics in statistical process control.

Keywords

Statistical process control · EWMA · CUSUM · Profile monitoring · Point clouds

Introduction

Variation control is an important goal in manufacturing. The main tool for variation control used in discrete part manufacturing industries up to the 1960s is developed by W. Shewhart in the 1920s

and is what is known today as statistical process control or SPC (Shewhart 1939). Shewhart's SPC model assumes that the process varies about a fixed mean and that consecutive observations from a process are independent, as follows:

$$Y_t = \mu_0 + \epsilon_t \quad (1)$$

in which μ_0 is the in-control process mean and ϵ_t is iid (independent identically distributed) white noise $\epsilon \stackrel{iid}{\sim} N(0, \sigma^2)$. The Shewhart model can be used in distinguishing assignable cause variation from common cause variation. For example, a mean change from μ_0 to $\mu_1 = \mu_0 + \delta$ (where δ is the unknown magnitude of change) or a variance increase from σ_0^2 to σ_1^2 at an unknown point in time can be detected as assignable causes.

The objective of this entry is to highlight some of the important references in the SPC methods applied to manufacturing and to discuss similarities and joint applications SPC has with automatic process control. We discuss in detail fundamental process monitoring topics including Shewhart's model, $\bar{X}$ and R control charts, EWMA and CUSUM charts, process monitoring for autocorrelated data, and integration of statistical and engineering (or automatic) control techniques. In addition, we present some of the more advanced SPC methods developed recently for monitoring profiles, surfaces, and point clouds. The literature on statistical process control and applications to engineering problems is vast; therefore no effort is made for an exhaustive review. More complete reviews of the literature on statistical process control and adjustment methods can be found in texts including Montgomery (2013), Ryan (2011), and Del Castillo (2002).

Shewhart Control Charts

Shewhart's $\bar{X}$ and R control charts are used for monitoring, respectively, the process mean and process variance to distinguish between

common cause and assignable causes of variation (Shewhart 1939). "Common cause" variation is the natural variability of the process due to uncontrollable factors in the environment that is not avoidable without substantial changes to the process. "Assignable cause" variation is due to unwanted disturbances or upsets to the process that can be detected and removed to produce acceptable quality products. When only common cause variation exists, the process is said to be operating "in statistical control." Assignable causes of variation include operator changes, machine calibration errors, or raw material variation between suppliers.

Another concept that is closely related to the Shewhart's model is process capability. Process capability indices are used to assess whether the process is operating in a satisfactory manner with respect to the engineering specifications. It is crucial to attain a stable process (by identifying and eliminating all assignable causes of variation) before undertaking such a capability analysis because only when the samples come from a stable probability distribution can the future behavior of the process be predicted "within probability limits determined by the common-cause system" (Box and Kramer 1992).

Figure 1 illustrates the two main phases, referred to as Phase I and Phase II, in constructing Shewhart charts (Sullivan 2002), using semiconductor lithography process data given in Montgomery (2013). It is desired to establish a statistical control of the width of the resist using $\bar{X}$ and R charts. Twenty-five preliminary subgroups, each of size five wafers, were taken at 1-hour intervals, and the resist width is measured. In Phase I, a "retrospective analysis" is conducted, in which a historical set of data from the process is analyzed to bring an initially out-of-control process into statistical control. Subgroups $y_1, \dots, y_n$ of size n are taken and subgroup average $\bar{y}$ is used to monitor process mean μ_0 , and the subgroup range is used to monitor standard deviation of the process mean $\sigma_{\bar{y}} = \sigma/\sqrt{n}$. The upper and lower control limits are found for the $\bar{X}$ chart

as $\{UCL, LCL\} = \mu_0 \pm L\sigma_{\bar{Y}}$ where L is a constant representing the width of the control limits. Commonly chosen three-sigma limits (i.e., $L = 3$) provide a probability $p = 0.0027$ that a single point falls outside the limits when process is in control (“false alarm probability”). Points that fall outside the control limits are investigated and if an assignable cause was identified, then this point is omitted, and control limits are recalculated. This is repeated until no further points plot outside the limits. In Phase II, a “prospective analysis” is conducted, in which these charts are used to detect shifts in the process mean and variability by taking and measuring a new subgroup from the process sequentially.

The $\bar{X}$ and R charts from Phase I data shown in Fig. 1a indicate statistical control; hence the computed control limits can be used for Phase II monitoring. Twenty additional subgroups (also of size 5) are taken in Phase II while the control charts are in use. The Phase II charts shown in Fig. 1b indicate that process variability is stable, but the process mean has shifted at subgroup 18. The general trend in the $\bar{X}$ chart indicates that process mean probably has shifted earlier, around subgroup 13.

EWMA, CUSUM, and Changepoint Estimation

Shewhart charts can detect large magnitude process upsets reasonably well; however, they are relatively slow to detect small shifts. In order

to reduce the reaction time for smaller shifts, a set of “runs” rules (e.g., two out of three runs beyond 2σ limits or four out of five runs beyond 1σ limits) has been proposed (Western Electric Company 1956). A more systematic method is to accumulate information over successive observations using CUSUM and EWMA statistics rather than basing the detection on a single sample. In the cumulative sum (CUSUM) chart, a running total $\sum_{i=1}^t (\bar{Y}_i - \mu_0)$ is plotted against subgroup number t , and a shift from the in-control mean μ_0 is signaled by an upward or downward linear trend in the plot. A two-sided CUSUM is defined as (Woodall et al. 2004):

$$S_t^{\pm} = \max\{\pm Z_t - k + S_{t-1}^{\pm}, 0\} \text{ for } t = 1, 2, \dots \quad (2)$$

where S_t^+ and S_t^- are the one-sided upper and lower CUSUMs, respectively, $Z_t = (\bar{Y}_t - \mu_0)/\sigma_{\bar{Y}}$ is the standardized subgroup average, $k = |\mu_1 - \mu_0|/(2\sigma)$ is the reference value, and μ_1 is the level of process mean to be detected. An out-of-control signal is given at the first t for which $S_t > h$ where h is a suitably chosen threshold, usually selected based on the desired average number of samples to signal an alarm, also called the Average Run Length (ARL). The recommended value for the threshold h is 4 or 5 (corresponding to four or five times the process standard deviation σ), and the value for the reference k is almost always taken as 0.5 (corresponding to shift size $|\mu_1 - \mu_0| = \sigma$) (Montgomery 2013).

Statistical Process Control in Manufacturing, Fig. 1 Shewhart $\bar{X}$ and R chart from (a) Phase I analysis (b) Phase II analysis

Another chart that accumulates deviations over several samples is the exponentially weighted moving average (EWMA) which is based on the statistic (Lucas and Saccucci 1990):

$$Z_t = \lambda \bar{Y}_t + (1 - \lambda)Z_{t-1} \quad (3)$$

where $0 < \lambda < 1$ is a smoothing constant. Smaller λ provides large smoothing (similar to a large subgroup size n in the Shewhart charts). The starting value is the in-control mean $Z_0 = \mu_0$. It can be shown that Z_t is a weighted average of all previous sample means, where the weights decrease geometrically with the age of the subgroup mean. The EWMA statistic is plotted against the control limits $\mu_0 \pm L\sigma_{\bar{Y}}\sqrt{(\lambda/(2-\lambda))[1 - (1-\lambda)^{2t}]}$. Shewhart charts that are effective for large shifts are more useful for Phase I, and CUSUM or EWMA charts that are effective for small shifts are more appropriate for Phase II.

We illustrate in Fig. 2 how to monitor a process with CUSUM and EWMA charts using the lithography data studied in the previous section. The in-control process mean and standard deviation μ_0 and σ are found from the Phase I data. CUSUM upper and lower statistics $S_t^\pm$ computed with Phase II data are plotted in Fig. 2a (reference value $k = 0.5$ and threshold $h = 4$ are used). The upper CUSUM statistic S_t^+ crosses the upper control limit indicating an upward shift at subgroup 15. The EWMA statistic applied with $\lambda = 0.2$ on Phase II data, shown Fig. 2b, crosses the upper control limit at subgroup 16. As it can be seen, both CUSUM and EWMA charts can improve the reaction times of the Shewhart chart (recall from Fig. 1b that Shewhart chart signaled at subgroup 18).

When a control chart signals an assignable cause, it does not indicate when the process change actually occurred. Estimating the instant of the change, or *change point* estimation, is especially useful in Phase I analysis where little is known about the process and it is important to identify and remove the out-of-control samples from consideration (Hawkins et al. 2003; Basseville and Nikiforov 1993; Pignatiello and Samuel 2001). In a change point

model, the process is modeled as:

$$\begin{aligned} Y_i &\sim N(\mu_1, \sigma^2) \text{ for } i = 1, 2, \dots, \tau \\ Y_i &\sim N(\mu_2, \sigma^2) \text{ for } i = \tau + 1, \dots, n \end{aligned} \quad (4)$$

where τ is the unknown change point, at which the in-control mean μ_1 is assumed to shift to a new value μ_2 assuming μ_1 and σ are known but μ_2 is unknown. A Generalized Likelihood Ratio (GLR) test statistic $\Lambda_t = \sum_{i=1}^t \log f_2(y_i)/f_1(y_i)$ is used to test the hypothesis of a change point against the null hypothesis that there is no change. Assuming normality $f(y) = 1/\sqrt{2\pi\sigma} \exp[-(y - \mu)^2/(2\sigma^2)]$ is the probability density function of the quality characteristic. The change point model is equivalent to the CUSUM chart when all parameters μ_1 , μ_2 , and σ are known a priori. For the lithography Phase II data in Fig. 1b, it can be shown that the change point can be estimated as subgroup 13.

SPC on Controlled and Autocorrelated Processes

It is well known that automatic control performance relies heavily on the accuracy of the process models. An active field of research in recent years is the monitoring of controlled systems using SPC charts (Box and Kramer 1992) in order to reduce the effect of model accuracy. Shewhart charts can be used to monitor the output of a feedback controlled process; however, as the controller effectively corrects the shift, only a short window of opportunity is available to detect the shift (Vander Wiel et al. 1992). Tsung and Tsui (2003) showed that monitoring the control actions gives better run length performance than monitoring the output for small- and medium-sized shifts, and monitoring the output gives better performance for large shifts. In monitoring controlled processes, measurements taken at short intervals with positive autocorrelation usually inflate the rate of false alarms (Harris and Ross 1991). Widening the control limits and monitoring the residuals of a time-series model fitted to the observations are suggested strategies

Statistical Process Control in Manufacturing, Fig. 2 Phase II charts for lithography data (a) CUSUM chart and (b) EWMA chart

Statistical Process Control in Manufacturing, Fig. 3 (a) Shewhart chart for autocorrelated process. (b) Shewhart chart for residuals

to reduce the number of false alarms when monitoring positively autocorrelated processes (Alwan and Roberts 1988).

To illustrate the effects of autocorrelation, we consider simulated data from an autoregressive moving average ARMA(1,1) time-series disturbance process $D_t = 0.8D_{t-1} + \epsilon_t - 0.3\epsilon_{t-1}$ (Box et al. 1994) defined with the white noise process $\epsilon_t \stackrel{iid}{\sim} N(0, 1^2)$ (with in-control mean $\mu_0 = 0$ and variance $\sigma_D^2 = 1.694$). Figure 3a shows a realization of the process monitored with a Shewhart chart (control limits at $\mu_0 \pm 3\sigma_D$). Due to autocorrelation, false alarms are signaled at samples 81 to 83. Figure 3b shows the control chart monitoring of the residuals of an ARMA(1,1) model. Residuals (standard normal with mean 0 and variance 1) are not autocorrelated, so the Shewhart chart for residuals does not signal any false alarms.

We illustrate monitoring of controlled processes with simulated data from a transfer function model $Y_t = 2X_{t-1} + D_t$ where X_t are the adjustments made on the process. A proportional integral control rule $X_t = -0.1Y_t - 0.15 \sum_{i=1}^t Y_i$ is employed, and the disturbance D_t is assumed to follow the ARMA model considered earlier. As an assignable cause, the mean of the disturbance was shifted by a magnitude of $3\sigma_D$ after sample 100. Figure 4 shows the Shewhart charts monitoring the output Y_t and the input X_t . The effect of assignable cause (at sample 100) on the output is quickly removed by the controller; however, a sustained shift remains in the control input. The control chart for the input Fig. 4b signals the first alarm at sample 101 (much quicker) than the control chart for the output Fig. 4a which signals at sample 110.

SPC for Monitoring Surface, Image, and Point Cloud Data

As advanced measurement technologies are more commonly utilized in manufacturing processes, more recent applications of SPC have focused on handling high-dimensional and more complex data in a more effective way. One such measurement technology is the three-dimensional (3D) laser scanners that can rapidly provide tens of thousands of data points, also called point clouds, allowing the entire surface geometry of a discrete part to be measured and represented quickly and inexpensively (Wells et al. 2013). Compared to the more traditional coordinate measurement systems (CMMs) that measure the product only at a limited number of points, such high-density measurement technologies allow one to monitor the entire surface and detect the occurrence of a large variety of fault patterns. Another emerging area is the use of high-density data in image and surface monitoring (Megahed et al. 2011; Qiu 2018; Colosimo 2018). Machine vision systems had long been applied as medical diagnosis tools using technologies including ultrasound, functional MRI, and X-ray (Qiu 2018). However, industrial applications for in-line process monitoring of surfaces in manufacturing have attracted an increasing interest in the recent years. Image-based SPC relies on sequences of images or videos taken from a process or a product with the goal

of quickly detecting and localizing the onset of product defects or process abnormalities by comparing a current image to the image that corresponds to an in-control state. Some applications include defect detection in textiles (Megahed et al. 2011), additively manufactured parts (Colosimo 2018), and liquid crystal display (LCD) surfaces (Jiang et al. 2005).

In the high-dimensional data environments, the quality of the product is often more adequately characterized by a relationship between the quality characteristic and one or more explanatory variables. For example in semiconductor manufacturing, the oxide thickness (quality characteristic) on a semiconductor wafer surface can be measured at given spatial locations (explanatory variable) (Gardner et al. 1997). In such cases, at each sampling instant, a set of measurements of the quality characteristic, as opposed to only one, is observed from the product under a range of explanatory variable values. In profile monitoring the goal is to represent the functional relationship between the quality characteristic and the explanatory variables by a statistical model, referred to as a “profile”, and detect any type of shift in the function (Woodall et al. 2004). Other examples of profiles in manufacturing include radius measurements in a turning process (Colosimo et al. 2014) and stamping force as a function of crank-arm angle in a steel stamping operation (Jin and Shi 2001). In the area of surface monitoring, both two- and three-dimensional

shapes of products are monitored using profile monitoring techniques. It has been shown that representing the surface shape with a functional model can be more efficient than the standard image monitoring approaches. A fundamental difference is that image intensity functions have jumps and singularities, but in profile monitoring, the surfaces are often assumed to be continuous (Qiu 2018).

Monitoring using 3D point clouds and image data has been studied based on the profile monitoring framework. Wells et al. (2013) proposed to monitor the deviations between points scanned from each actual part and the Computer Aided Design (CAD) surface of the part after the part and nominal are registered. This may be computationally expensive and may increase the variance due to the registration step, as pointed out by Del Castillo and Zhao (2019, to appear) and Zhao and del Castillo (2019), who propose instead a registration-free approach based on monitoring the spectrum of the point cloud. Spatiotemporal approaches were proposed by Megahed et al. (2011) to detect both the spatial location and size of a defect and the changepoint in time within the image stream. Jiang et al. (2005) developed

a spatial control chart to inspect uniformity of LCD monitors and detect type, size, and location of defects.

As an illustration of how SPC is applied in a surface monitoring problem, Fig. 5 shows simulated results for the cylindricity monitoring problem studied in Colosimo et al. (2014). These authors considered monitoring the cylindricity of carbon steel bars machined by lathe turning, and the goal is to signal an alarm when a “form error” is encountered. The cylindrical surface profiles are modeled using Gaussian processes (GP), and the GP-predicted deviations of the surface from the in-control pattern are monitored to detect form errors. Figure 5a shows the regular grid on which the surface coordinates are measured (e.g., using a 3D scanner). Figure 5b shows a case with only random measurement variation and no form error, and Fig. 5c shows a case with a form error (a “tapered” shape) which can be detected and identified with a surface monitoring approach. Colosimo et al. (2014) report that the use of GP-based methods can improve the detection speed of out-of-control states by up to 80 times compared to the current industrial practice.

Summary and Future Directions

In this entry we reviewed some of the commonly used statistical process control (SPC) methods for manufacturing systems. We reviewed several fundamental SPC concepts, including Phase I and Phase II monitoring and the Shewhart, EWMA, and CUSUM control charts. In addition, we highlighted several, more recently developed high-dimensional monitoring methods applied for profiles, surfaces, images, and point clouds. The concepts were illustrated where possible, with numerical examples. Other important SPC research areas that have not been reviewed in this entry include multivariate methods for monitoring processes with multiple quality characteristics taking advantage of relationships among them (Lowry and Montgomery 1995), multistage monitoring for processes with multiple processing steps and variation transmission (Tsung et al. 2008) and permutation-based nonparametric SPC methods that are robust to distributional assumptions (Chen et al. 2016; Capizzi and Masarotto 2017).

Stochastic Adaptive Control

Tyrone Duncan and Bozena Pasik-Duncan
Department of Mathematics, University of
Kansas, Lawrence, KS, USA

Abstract

Stochastic adaptive control focuses on the control of partially known stochastic systems. These systems occur in both continuous and discrete time and are described by Markov chains, stochastic difference equations, and stochastic differential equations. Two major goals for the solutions are self-tuning and self-optimizing. These two goals are typically determined asymptotically so that self-optimality denotes the convergence of the average costs to the optimal long-run average cost for the true system.

Keywords

Stochastic systems · Stochastic control · System identification · Parameter estimation · Adaptive control

Introduction

Stochastic adaptive control denotes the control of partially known stochastic control systems. The stochastic control systems can be described by discrete- or continuous-time Markov chains or Markov processes, linear and nonlinear difference equations, and linear and nonlinear stochastic differential equations. The solution of a stochastic adaptive control problem typically requires the identification of the partially known stochastic system and the simultaneous control of the partially known system using the information from the concurrent identification scheme. Two desirable goals for the solution of a stochastic adaptive control problem are called self-tuning and self-optimality. Self-tuning denotes the convergence of the family of adaptive controls indexed by time to the optimal control for the true system. Self-optimizing denotes the convergence of the long-run average costs to the optimal long-run average cost for the true system. Typically to achieve the self-optimality, it is important that the family of parameter estimators from the identification scheme be strongly consistent, that is, this family converges (almost surely) to the true parameter values. Thus, with self-optimality, asymptotically a partially known system can be controlled as well as the corresponding known system.

Motivation and Background

In almost every formulation of a stochastic control problem from a physical system, the physical system is incompletely known so the stochastic system model is only partially known. This lack of knowledge can often be described by some unknown parameters for a mathematical model, and furthermore the noise inputs for the model can describe unmodeled dynamics or perturbations to the physical system. The lack of knowledge of some parameters of the model can be modeled either by random variables with known prior distributions or as fixed unknown values. The former description requires Bayesian estimation, and the latter description requires parameter

estimation such as least squares, weighted least squares or maximum likelihood.

Stochastic adaptive control arose as a natural evolution from the results in stochastic control; in fact stochastic adaptive control is an application of stochastic control, and in particular stochastic adaptive control developed from some well-known control problems (Davis and Vinter 1985). The optimal control of Markov chains had been developed for some time, so it was natural to investigate the adaptive control of Markov chains. Mandl (1973) was probably the first to consider this adaptive control problem in generality. His conditions for strong consistency of a family of estimators were fairly restrictive. Borkar and Varaiya (1982) simplified the conditions for the estimation part of the problem by only requiring convergence of the estimators of the parameters so that the resulting transition probabilities of the Markov chain are identical to the transition probabilities for the true optimal solution.

A second major direction for stochastic adaptive control is described by ARMAX (autoregressive moving average with exogenous inputs) models. These are discrete-time models that can be described in terms of polynomials in a time shift operator. A closely related and often equivalent model is multidimensional linear difference equations in a state-space form. Since the solution of the infinite time horizon discrete-time stochastic control problem was available in the late 1950s, it was natural to consider the corresponding adaptive control problem. Methods such as least squares, weighted least squares, maximum likelihood, and stochastic approximation were used for parameter identification and a certainty equivalence adaptive control for the system, that is, using the current estimate of the parameters as the true parameters to verify self-optimality. An important development in stochastic adaptive control is a result called the self-tuning regulator where the convergence of estimators of unknown parameters implied the convergence of the output tracking error (Astrom and Wittenmark 1973; Goodwin et al. 1981; Guo 1995, 1996; Guo and Chen 1991; Kumar 1990).

A number of monographs treat various aspects of stochastic adaptive control problems, e.g.,

Astrom and Wittenmark 1989; Chen and Guo 1991; Kumar and Varaiya 1986; Ljung and Soderstrom 1983. An extensive survey article on the early years of stochastic adaptive control is given by Kumar (1985).

Structures and Approaches

Various requirements can be made for the adaptive control of a stochastic system. However it is important to understand the stochastic systems. It can only be required that the family of adaptive controls is stabilizing the unknown system or that the family of adaptive controls converges to the optimal control for the true system or that the family of adaptive controls has a long-run average cost that is equal to the optimal average cost for the true system. The identification part of the adaptive control problem can be Bayesian estimation (Kumar 1990) if the parameters are assumed to be random variables or parameter estimation (Bercu 1995; Lai and Wei 1982) if the parameters are assumed to be unknown constants. The identification scheme may also incorporate information about the running cost.

For linear systems with white noise inputs, it is well-known to use least squares (or equivalently maximum likelihood) estimation to estimate parameters. However, for stochastic adaptive control problems, the sufficient conditions for the family of estimators to be strongly consistent are fairly restrictive (e.g., Lai and Wei 1982), and in fact the family of estimators may not even converge in general. A weighted least squares estimation scheme (Bercu 1995) can guarantee convergence of the family of estimators without the need of any excitation condition (Guo 1996). Some other estimation methods are stochastic approximation (Guo and Chen 1991) and an ordinary differential equation approach (Ljung and Soderstrom 1983). For discrete-time nonlinear systems, a family of strongly consistent estimators may not converge sufficiently rapidly even to stabilize the nonlinear system (Guo 1997).

The study of stochastic adaptive control of continuous-time linear stochastic systems with long-run average quadratic costs developed

somewhat after the corresponding discrete-time study (e.g., Duncan and Pasik-Duncan 1990). A solution with basically the natural assumptions from the solution of the known system problem using a weighted least squares identification scheme is given in Duncan et al. (1999).

Another family of stochastic adaptive control problems is described by linear stochastic equations in an infinite dimensional Hilbert space. These models can describe stochastic partial differential equations and stochastic hereditary differential equations. Some linear-quadratic-Gaussian control problems have been solved, and these solutions have been used to solve some corresponding stochastic adaptive control problems (e.g., Duncan et al. 1994a).

Optimal control methods such as Hamilton-Jacobi-Bellman equations and a stochastic maximum principle have been used to solve stochastic control problems described by nonlinear stochastic differential equations (Fleming and Rishel 1975). Thus, it was natural to consider stochastic adaptive control problems for these systems. The results are more limited than the results for linear stochastic systems (e.g., Duncan et al. 1994b).

Other stochastic adaptive control problems have recently emerged that are modeled by multi-agents, such as mean field stochastic adaptive control problems (e.g., Nourian et al. 2012).

A Detailed Example: Adaptive Linear-Quadratic-Gaussian Control

This example is a model that is the most well-known continuous-time stochastic adaptive control problem. Likewise for a known continuous-time system, this stochastic control problem is the most basic and well-known solvable problem. The controlled system is described by the following multidimensional stochastic differential equation:

$$\begin{aligned} dX(t) &= AX(t)dt + BU(t)dt + CdW(t) \\ X(0) &= X_0 \end{aligned}$$

where $X(t) \in \mathbb{R}^n$, $U(t) \in \mathbb{R}^m$, and $(W(t), t \geq 0)$ is an $\mathbb{R}^p$ -valued standard Brownian motion and (A, B, C) are appropriate linear transformations. $X(t)$ is the state of the system at time t , and $U(t)$ is the control at time t . It is assumed that A, B , and C are unknown linear transformations. The cost functional, $J(\cdot)$, is a long-run average (ergodic) quadratic cost functional that is given by

$$\begin{aligned} J(U) &= \limsup_{T \rightarrow \infty} \frac{1}{T} \int_0^T \langle QX(t), X(t) \rangle \\ &\quad + \langle RU(t), U(t) \rangle dt \end{aligned}$$

where $R > 0$ and $Q \geq 0$ are symmetric linear transformations and $\langle \cdot, \cdot \rangle$ is the canonical inner product in the appropriate Euclidean space. The standard assumptions for the control of the known system are made also for the adaptive control problem, that is, the pair (A, B) is controllable, and $(A, Q^{\frac{1}{2}})$ is observable. An optimal control for the known system is

$$U^0(t) = -R^{-1}B^T S X(t)$$

where S is the unique positive, symmetric solution of the following algebraic Riccati equation:

$$A^T S + SA - SBR^{-1}B^T S + Q = 0$$

The optimal cost is

$$J(U^0) = \text{tr}(C^T S C)$$

The unknown quantity $C^T C$ can be identified given $(X(t), t \in [a, b])$ for $a < b$ arbitrary from the quadratic variation of Brownian motion, so the identification of C is not considered here. Since it is assumed that the pair (A, B) is unknown, the system equation is rewritten in the following form:

$$dX(t) = \theta^T \varphi(t)dt + CdW(t)$$

where $\theta^T = [A \ B]$ and $\varphi^T(t) = [X^T(t) \ U^T(t)]$. A family of continuous-time weighted least squares recursive estimators $(\theta(t), t \geq 0)$ of

θ is given by the following stochastic equation (Guo 1996):

$$\begin{aligned}d\theta(t) &= a(t)P(t)\varphi(t)[dX^T(t) - \varphi^T(t)\theta(t)dt] \\dP(t) &= -a(t)P(t)\varphi(t)\varphi^T(t)P(t)dt\end{aligned}$$

where $(a(t), t \geq 0)$ is a suitable family of positive stochastic weights (Duncan et al. 1999). A family of estimates $(\hat{\theta}(t), t \geq 0)$ is obtained from $(\theta(t), t \geq 0)$ and is expressed as $\hat{\theta}(t) = [A(t) B(t)]$ (Duncan et al. 1999). A process $(S(t), t \geq 0)$ is obtained using $(A(t), B(t))$ in place of (A, B) by solving the following stochastic algebraic Riccati equation for each $t \geq 0$:

$$\begin{aligned}A^T(t)S(t) + S(t)A(t) \\- S(t)B(t)R^{-1}B^T(t)S(t) + Q = 0\end{aligned}$$

A certainty equivalence method is used to determine the control, that is, it is assumed that the pair $(A(t), B(t))$ is the correct pair for the true system, so a certainty equivalence adaptive control $U(t)$ is given by

$$U(t) = R^{-1}B^T S(t)X(t)$$

It can be shown (Duncan et al. 1999) that the family of estimators $((A(t), B(t)), t \geq 0)$ is strongly consistent and that the family of adaptive controls given by the previous equality is self-optimizing, that is, the long-run average cost $J(U) = J(U^0) = \text{tr}(C^T S C)$ where S is the solution of the algebraic Riccati equation for the true system.

Future Directions

A number of important directions for stochastic adaptive control are easily identified. Only four of them are described briefly here. The adaptive control of the partially observed linear-quadratic-Gaussian control problem (Fleming and Rishel 1975) is a major problem to be solved using the same assumptions of controllability and observability as for the known system. This

problem is a generalization of the example given above where the output (linear transformation) of the system is observed with additive noise and the family of controls is restricted to depend only on these observations. Another major direction is to modify the detailed example above by replacing the Brownian motion in the stochastic equation for the state by an arbitrary fractional Brownian motion (Duncan and Pasik-Duncan 2013) or by an arbitrary square-integrable stochastic process with continuous sample paths. For this latter problem it is necessary to use recent results for optimal controls for the true system and to have strongly consistent families of estimators. A third major direction is the adaptive control of nonlinear stochastic systems. A fourth major direction is the adaptive control of mean field games (Huang et al. 2006; Lasry and Lions 2007; Duncan and Tembine 2018).

Abstract

The topic of stochastic approximation (SA) and its pioneer algorithm (the Robbins-Monro (RM) algorithm) with methods for its convergence analysis are described. Algorithms modified from the RM algorithm such as the SA algorithm with constant step-size and the SA algorithm with expanding truncations (SAAWET) are demonstrated. Applications of SA to problems arising from optimization, system identification, adaptive control, signal processing, etc. are presented.

Keywords

Robbins-Monro algorithm · Optimization · Expanding truncations · System identification · Control · Signal processing · Distributed algorithm

Introduction

Estimating unknown parameters is ubiquitous in systems and control. For a fixed parameter, say x^0 , there are infinitely many functions having x^0 as its root. Let x^0 be the root of a function $f(\cdot) : f(x^0) = 0$. If $f(\cdot)$ is known, then there are many well-known numerical methods, which can be used to search its roots. In practice, however, $f(\cdot)$ possibly is not exactly known, and the value of $f(x)$ at any x may be available only with errors. In other words, at any time $k + 1$, the available observation about $f(x_k)$ is

$$y_{k+1} = f(x_k) + \epsilon_{k+1}, \quad (1)$$

where ϵ_{k+1} is the observation error. The topic of SA is to design algorithms which recursively generate $x_1, x_2, \dots$ converging to x^0 , starting from an initial value x_0 .

The first such an algorithm Robbins and Monro (1951) is presented in section “[RM Algorithm and Its Convergence Analysis](#).” SA algorithms with constant step-size and with expanding truncations are given in section “[SA Algorithms Modified from RM Algorithm](#).” Applications of SA to optimization and to problems from systems and control are presented in sections “[Application of SA to Optimization](#)” and “[Application of SA to Systems and Control](#),” respectively.

RM Algorithm and Its Convergence Analysis

To seek the roots of an unknown function $f(\cdot) : R^l \rightarrow R^l$ by using the observation (1), the following recursive algorithm is proposed in Robbins and Monro (1951):

$$x_{k+1} = x_k + a_k y_{k+1} \quad \text{with}$$

$$a_k > 0, \quad a_k \rightarrow 0, \quad \text{and} \quad \sum_{k=1}^{\infty} a_k = \infty. \quad (2)$$

This algorithm is called the RM algorithm and the function $f(\cdot)$ the regression function. The root set of $f(\cdot)$ is denoted by $J \triangleq \{x \in R^l : f(x) = 0\}$, which may be a singleton x^0 . However, the algorithm is not necessary to have the desired convergence. For example, in the case where $f(x) = (x - 10)^3$ and $x_0 = 0$, the RM algorithm never converges to the root 10, even if $\epsilon_k \equiv 0$.

For convergence analysis of the RM algorithm, there are the probabilistic method and the ODE (ordinary differential equation) method. In what follows $(\Omega, \mathcal{F}, P)$ denotes the probability space, and algorithms are considered for fixed $\omega \in \Omega$.

Probabilistic Method

This approach is based on probabilistic assumptions on the observation noise $\{\epsilon_k\}$. For example,

if $\{\epsilon_k\}$ is assumed to be a sequence of zero-mean mutually independent and identically distributed (iid) random vectors with finite second moment, then the resulting sequence of estimates $\{x_k\}$ is a Markov process. In addition, assume that (i) there exists a Lyapunov function $v(\cdot) : R^l \rightarrow R$ such that $v(x) > 0 \quad \forall x \neq x^0$, $v(x^0) = 0$, $v(x) \rightarrow \infty$ as $\|x\| \rightarrow \infty$, and

$$\sup_{\|x - x^0\| > \epsilon} v_x^T(x) f(x) < 0 \quad \forall \epsilon > 0$$

with $v_x(x)$ being the gradient of $v(\cdot)$; and (ii) $\sum_{i=1}^{\infty} a_i^2 < \infty$, and $\|f(x)\|^2 < cv(x)$ for some constant c . Then, $x_k \rightarrow x^0$ with probability 1. If $v(x)$ is a quadratic function, then the last condition implies that as $\|x\| \rightarrow \infty$, $\|f(x)\|$ should not grow up faster than linearly.

The observation noise $\{\epsilon_k\}$ may be a martingale difference sequence, a Markov chain, or a stochastic process with some specified properties, in particular, it may depend on the past estimates. Nevelson and Khasminskii (1976). Then, various tools developed in stochastic analysis can be applied to consider the convergence problem of $\{x_k\}$. The convergence with probability one or in the mean-square sense are usually expected to obtain. However, for this the probabilistic assumptions are often hard to be met in applications.

In addition to convergence, the convergence rate, asymptotic normality, and asymptotic efficiency can also be derived (Nevelson and Khasminskii 1976; Chen 2002). To achieve asymptotic efficiency, the averaging technique is introduced in Polyak and Judisky (1992).

ODE Method

To avoid the restrictive conditions used by the probabilistic method for convergence analysis, the ODE method is introduced in Kushner and Clark (1978) and Ljung (1977). The probabilistic assumptions made on $\{\epsilon_k\}$ are replaced by the following path-wise condition:

$$\lim_{T \rightarrow 0} \limsup_{n \rightarrow \infty} \frac{1}{T} \left\| \sum_{k=n}^{m(n,T)} a_i \epsilon_{i+1} \right\| = 0, \quad (3)$$

$$a_k \epsilon_{k+1} \xrightarrow[k \rightarrow \infty]{} 0,$$

where

$$m(k, T) \triangleq \max \left\{ m : \sum_{i=k}^m a_i \leq T \right\}. \quad (4)$$

It is clear that (3) holds whenever either $\epsilon_{k+1} \xrightarrow[k \rightarrow \infty]{} 0$ or $\sum_{i=1}^{\infty} a_i \epsilon_{i+1} < \infty$. Further, the growth rate restriction on $f(\cdot)$ is replaced by its continuity.

Assume the estimates $\{x_k\}$ generated by the RM algorithm are bounded. Interpolate them into a continuous function $x^0(t)$ with interpolating length $\{a_k\}$. Define $t_n = \sum_{i=0}^{n-1} a_i$, $x^n(t) = x^0(t + t_n)$ for $t \geq -t_n$ and $x^n(t) = x_0$ for $t \leq -t_n$. With possible exception of a set with probability zero, the limit $x(\cdot)$ of any convergent subsequence of $\{x^n(\cdot)\}$ satisfies the ODE $\frac{dx(t)}{dt} = f(x(t))$. Let x^0 be its stable equilibrium with domain of attraction $DA(x^0)$. If the sequence $\{x_k\}$ enters infinitely often a compact subset of $DA(x^0)$, then $x_k \xrightarrow[k \rightarrow \infty]{} x^0$ (Kushner and Clark 1978). Without any stability assumption on the ODE, it can still be established that the limit set of $\{x_k\}$ is a connected set internally chain-recurrent for the ODE (Benaim 1996).

It is noticed that in comparison with the probabilistic method, the ODE method requires much weaker conditions on both $\{\epsilon_k\}$ and $f(\cdot)$. So, it is widely used in applications (Benveniste et al. 1990).

SA Algorithms Modified from RM Algorithm

Algorithm with Constant Step-Size

In the RM algorithm, the step-size $\{a_k\}$ is tending to zero. When the constant step-size, i.e., $a_k \equiv \epsilon$ with $\epsilon > 0$, is used, write x_k as x_k^ϵ . Then $x_{k+1}^\epsilon = x_0^\epsilon + \epsilon \sum_{i=0}^k [f(x_i^\epsilon) + \epsilon_{i+1}]$, which, in general, cannot converge path-wisely as $k \rightarrow \infty$.

By the weak convergence method, the obtained sequence $\{x_k^\epsilon\}$ is interpolated to a piece-wisely constant function $x^\epsilon(t) \triangleq x_k^\epsilon$ for $t \in [\epsilon k, \epsilon(k+1))$, and it is shown that as $\epsilon \rightarrow 0$, $x^\epsilon(\cdot)$ weakly converges to $x(\cdot)$ which is a solution to ODE $\dot{x}(t) = f(x(t))$, $x(0) = x_0$. Further, if x^0 is its unique asymptotically stable point, then the distance between $\{x^\epsilon(t_\epsilon + \cdot)\}$ and x^0 tends to zero in probability, whenever $t_\epsilon \rightarrow \infty$ as $\epsilon \rightarrow 0$. Under some additional conditions, it appears that $E\|x_n^\epsilon - x^0\| = O(\sqrt{\epsilon})$, and as $\epsilon \rightarrow 0$ the limit for the interpolated function of $\{\frac{x_n^\epsilon - x^0}{\sqrt{\epsilon}}\}$ is a solution to a stochastic differential equation driven by a standard Wiener process (Kushner and Yin 2003).

It is noticed that the stochastic gradient descent algorithm used in Goodfellow et al. (2016) for deep learning is an SA algorithm with constant step-size.

SA Algorithm with Expanding Truncations (SAAWET)

In the case where a region the sought-for root x^0 belongs to is known, then a truncated RM algorithm can be defined so that the estimates generated by the algorithm may path-wisely converge to x^0 .

However, the availability of the region and the boundedness assumption on $\{x_k\}$ greatly prevent SA algorithm from applications. To overcome the difficulty, the RM algorithm is truncated, but the truncation bound is not fixed but adaptively selected.

Let $\{M_k\}$ be a sequence of positive numbers increasingly diverging to infinity, and let x^* be a fixed point in R^l . With an arbitrarily fixed initial value x_0 , SAAWET is recursively defined as follows (Chen and Zhu 1986):

$$x_{k+1} = (x_k + a_k y_{k+1}) I_{[\|x_k + a_k y_{k+1}\| \leq M_{\sigma_k}]} + x^* I_{[\|x_k + a_k y_{k+1}\| > M_{\sigma_k}]}, \quad (5)$$

$$\sigma_k = \sum_{i=1}^{k-1} I_{[\|x_i + a_i y_{i+1}\| > M_{\sigma_i}]}, \quad \sigma_0 = 0, \quad (6)$$

where $I_{[A]}$ is the indicator of an ω -set A : $I_{[A]} = 1$ if $\omega \in A$, and $I_{[A]} = 0$ if $\omega \notin A$. The observation noise ϵ_{k+1} may depend on x_k .

Assume the following conditions: A1: $a_k > 0$, $a_k \xrightarrow[k \rightarrow \infty]{} 0$, and $\sum_{k=1}^{\infty} a_k = \infty$; A2: There exists a continuously differentiable function $v(\cdot) : R^l \rightarrow R$ such that $\sup_{\delta \leq d(x, J) \leq \Delta} f^T(x) v_x(x) < 0$ for any $\Delta > \delta > 0$, where $d(x, J) \triangleq \inf_y \{\|x - y\| : y \in J\}$, $J \triangleq \{x : f(x) = 0\}$, and $v_x(\cdot)$ denotes the gradient of $v(\cdot)$. Further, $v(J) \triangleq \{v(x) : x \in J\}$ is nowhere dense, and x^* used in (5) is such that $v(x^*) < \inf_{\|x\|=c_0} v(x)$ with $\|x^*\| < c_0$ for some $c_0 > 0$; A3: $f(\cdot)$ is measurable and locally bounded.

Let the noise ϵ_{k+1} be given by $\epsilon_{k+1} = \epsilon_{k+1}(x_k, \omega)$, $\omega \in \Omega$, where $\epsilon_{k+1}(\cdot, \cdot) : (R^l \times \Omega, \mathcal{B}^l \times \mathcal{F}) \rightarrow (R^l \times \mathcal{B}^l)$ is a measurable function defined on the product space.

Further, assume

A4: For the fixed sample path ω under consideration, the following limit takes place:

$$\lim_{T \rightarrow 0} \limsup_{k \rightarrow \infty} \frac{1}{T} \left\| \sum_{i=n_k}^{m(n_k, T_k)} a_i \epsilon_{i+1}(x_i(\omega), \omega) \right\| = 0 \quad \forall T_k \in [0, T] \quad (7)$$

along subscripts $\{n_k\}$ of any convergent subsequence $\{x_{n_k}(\omega)\}$ of $\{x_k(\omega)\}$.

General Convergence Theorem 1 (Chen 2002)

Let $\{x_k\}$ be given by (5) and (6) with a given initial value x_0 . Assume A1–A3 hold. Then, $d(x_k, J) \xrightarrow[k \rightarrow \infty]{} 0$ for any sample path ω for which A4 holds.

If the root set is a singleton $J = x^0$, further if $f(\cdot)$ is continuous at x^0 , then under A1–A3 for $x_k \xrightarrow[k \rightarrow \infty]{} x^0$ the necessary and sufficient condition is that ϵ_k can be decomposed into two parts $\epsilon_k = \epsilon_k^{(1)} + \epsilon_k^{(2)}$ such that $\epsilon_k^{(1)} \xrightarrow[k \rightarrow \infty]{} 0$ and $\sum_{i=1}^{\infty} a_i \epsilon_{i+1}^{(2)} < \infty$ (Wang et al. 1996).

Application of SA to Optimization

Kiefer-Wolfowitz Algorithm and Its Randomization

Searching extremums of a function $L(x)$, $x \in R^l$ when its gradient $L_x(x) \triangleq f(x)$ can be observed (possibly with noise) is the topic of SA consisting in finding the root set $J \triangleq \{x : f(x) = 0\}$. The problem is how to proceed when only the function $L(\cdot)$ itself rather than its gradient can be observed. Let x_k be the estimate at time k for the minimizer (maximizer) of $L(\cdot)$, and let $y_{k+1}^+ = L(x_k^+) + \xi_{k+1}^+$, $y_{k+1}^- = L(x_k^-) + \xi_{k+1}^-$ be two observations of $L(\cdot)$ at time $k+1$ with noises ξ_{k+1}^+ and ξ_{k+1}^- , respectively, where $x_k^+ = [x_k^1, \dots, x_k^{i-1}, x_k^i + c_k, x_k^{i+1}, \dots, x_k^l]^T$, and $x_k^- = [x_k^1, \dots, x_k^{i-1}, x_k^i - c_k, x_k^{i+1}, \dots, x_k^l]^T$.

Then, $y_{k+1}^i \triangleq \frac{y_{k+1}^+ - y_{k+1}^-}{2c_k}$ can naturally serve as the observation of $f_i(x_k)$, the i th component of the gradient $L_x(x) (\triangleq f(x))$. Thus, $y_{k+1} \triangleq [y_{k+1}^1, \dots, y_{k+1}^l]^T = f(x_k) + \epsilon_{k+1}$, where $\epsilon_{k+1} \in R^l$ with i th component equal to

$$\frac{L(x_k^+) - L(x_k^-)}{2c_k} - f_i(x_k) + \frac{\xi_{k+1}^+ - \xi_{k+1}^-}{2c_k}.$$

The resulting RM algorithm for searching extremum is called Kiefer-Wolfowitz (KW) algorithm (Kiefer and Wolfowitz 1952). The KW algorithm may fall into a local attraction domain of L , and for the global optimization, the simulating annealing method may be applied, but it provides convergence in probability only. The KW algorithm combined with initial value selection incorporated with some switch mechanism may solve the global optimization problem with probability one (Fang and Chen 2000).

It is noticed that each updating requires $2l$ observations, which may cause difficulty when l is large. A randomized version is proposed in Spall (1992) consisting in replacing the component-wise perturbations described above with simultaneous random perturbations, i.e., for a recursion only two observations $y_{k+1}^+ = L(x_k +$

$c_k \Delta_k) + \xi_{k+1}^+$ and $y_{k+1}^- = L(x_k - c_k \Delta_k) + \xi_{k+1}^-$ are needed, where $\Delta_k \in R^l$ with iid components Δ_k^i with both $|\Delta_k^i|$ and $|\frac{1}{\Delta_k^i}|$ bounded by a constant and $E \frac{1}{\Delta_k^i} = 0$. The convergence analysis is given in Spall (1992), while the version with expanding truncations is given in Chen et al. (1999).

In connection with the constrained optimization, the constrained or projected algorithms are proposed (Kushner and Clark 1978; Kushner and Yin 2003).

Distributed Stochastic Optimization

Let a network consist of N agents. In some cases, for example, if the time delays caused by information exchange among agents are not negligible, or the computation time spent on one step recursion is not the same for different agents, then it is natural to consider the asynchronous SA (Borkar 1998; Tsitsiklis 1994) in order to solve the optimization problem. SAAWET works well in the asynchronous case, but the truncation mechanism should be adjusted in accordance with multi-agents (Fang and Chen 2001).

Stochastic optimization and SA also work when the multi-agent system is equipped with a graph describing the information exchange among agents: each agent can exchange information only with its neighbors (Bianchi et al. 2013; Lei and Chen 2020; Lei et al. 2018). For distributed stochastic optimization subject to a global constraint, an SA-based distributed primal-dual algorithm is proposed (Lei et al. 2018) for a cost function being a sum of local functions. Each agent updates its estimate by using the local observations and the information derived from neighboring agents. The estimates generated by the algorithm at all agents pathwisely reach a consensus belonging to the optimal solution set.

Application of SA to Systems and Control

Parameter Estimation by SA

As mentioned in Introduction, the estimated parameter denoted by x^0 may be treated as a root

of an unknown regression function $f(\cdot)$, e.g., $f(x) = x - x^0$, $f(x) = \sin(\|x - x^0\|)$, $f(x) = e^x \|x - x^0\|^3$, etc. Since the selection of $\{a_k\}$ and $f(\cdot)$ is at the user's disposal, satisfaction of A1-A3 in 3.2 is not a problem when SAAWET is applied. The observation y_{k+1} at time $k + 1$ means the information available at time $k + 1$ about x^0 including the estimate x_k for x^0 at time k . It is clear that the observation y_{k+1} can always be written in the standard form (1) by setting $\epsilon_{k+1} \triangleq y_{k+1} - f(x_k)$.

Because of arbitrary selection of $f(\cdot)$, the error ϵ_{k+1} contains not only random noises but also structural errors, which cannot be expected to have a nice probabilistic property. However, the noise condition A4 can be verified for a large class of problems from systems and control, and the desired convergence results are obtained in the following cases:

In system identification the system coefficients and orders are estimated as parameters (Chen 2010, 2002; Mu and Chen 2014);

The values of a nonlinear function at any fixed points are treated as parameters to be estimated (Greblicki 2002; Mu and Chen 2013; Zhao et al. 2017; Chen and Zhao 2014);

For some control problems, in particular, for adaptive regulation, the optimal control performance is achieved at a time-invariant control, which serves as parameter to be estimated (Chen 2002; Chen and Zhao 2014).

This approach works well for some other problems described in Chen (2002) and Chen and Zhao (2014).

The key points of verification of A4 are to show that along any convergent subsequence $\{x_{n_k}\}$, $\{x_k\}$ in any small neighborhood of x_{n_k} suffer no truncation, and they are close to each other.

Other Applications

SA is well applied to solving problems from signal processing and communication. In fact, by using SA, the consensus is achieved for a networked nonlinear systems (Feng and Chen 2019); the adaptive filtering is realized by a sign algorithm (Chen and Yin 2003); the page

rank problem, adaptive pole assignment, blind identification, the principal component analysis (PCA) problem, and other problems are also appropriately solved (Chen 2002; Chen and Zhao 2014).

Summary and Future Directions

The RM algorithm and some of its modifications with their convergence properties are presented in the entry. They, in particular SAAWET, have successfully been applied to solving problems from systems and control and other related areas under reasonable conditions. It is natural to expect that more problems from various fields can be dealt with by using SAAWET. Concerning SAAWET itself, it is expected to consider how to prevent the algorithm from being stuck at an undesired point, how to reduce the number of truncations, and how to accelerate the convergence.

²Department of Biosystems Science and Engineering, Swiss Federal Institute of Technology at Zurich (ETHZ), Basel, Switzerland

Abstract

Conventional deterministic chemical kinetics often breaks down in the small volume of a living cell where cellular species (e.g., genes, mRNAs, etc.) exist in discrete, low copy numbers and react through reaction channels whose timing and order is random. In such an environment, a stochastic chemical kinetics framework that models species abundances as discrete random variables is more suitable. The resulting models consist of continuous-time discrete-state Markov chains. Here we describe how such models can be formulated and numerically simulated, and we present some of the key analysis techniques for studying such reactions.

Keywords

Chemical master equation · Gillespie algorithm · Moment dynamics · Stochastic biochemical reactions · Stochastic models

Introduction

The time evolution of a spatially homogeneous mixture of chemically reacting molecules is often modeled using a stochastic formulation, which takes into account the inherent randomness of thermal molecular motion. This formulation is important when modeling complex reactions inside living cells, where small populations of key reactants can set the stage for significant stochastic effects. In this entry, we review the basic stochastic model of chemical reactions and discuss the most common techniques used to simulate and analyze this model.

Stochastic Models of Chemical Reactions

We start by considering a set of N molecular species (reactants) $S_1, \dots, S_N$ that are confined to a fixed volume Ω . These species react through M possible reactions $R_1, \dots, R_M$. In this formulation of chemical kinetics, we shall assume that the system is in thermal equilibrium and is well mixed. Thus, the reacting molecules move due to their thermal energy. The population of the different reactants is described by a random process $X(t) = (X_1(t) \dots X_N(t))^T$, where $X_i(t)$ is a random variable that models the abundance (in terms of the number of copies) of molecules of species S_i in the system at time t . For the allowable reactions, we shall only consider elementary reactions. These could either be monomolecular, $S_i \rightarrow$ products, or bimolecular, $S_i + S_j \rightarrow$ products. Upon the firing of reaction R_k , a transition occurs from some state $X = \mathbf{x}_i$ right before the reaction fires to some other state $X = \mathbf{x}_i + \mathbf{s}_k$, which reflects the change in the population immediately after the reaction has fired. $\mathbf{s}_k$ is referred to as the *stoichiometric vector*. The set

Stochastic Description of Biochemical Networks, Table 1 Propensity functions for elementary reactions. The constants c , c' , and c'' are related to k , k' , and k'' , the reaction rate constants from *deterministic* mass-action kinetics. Indeed it can be shown that $c = k$, $c' = k'/\Omega$, and $c'' = 2k''/\Omega$

Reaction type	Propensity function
$S_i \rightarrow \text{Products}$	$c x_i$
$S_i + S_j \rightarrow \text{Products} \quad (i \neq j)$	$c' x_i x_j$
$S_i + S_i \rightarrow \text{Products}$	$c'' x_i (x_i - 1)/2$

of allowable M reactions defines the so-called stoichiometry matrix:

$$S = [s_1 \cdots s_M].$$

To each reaction R_k , we associate a *propensity function*, $w_k(\mathbf{x})$ that describes the rate of that reaction. More precisely, $w_k(\mathbf{x})h$ is the probability that, given the system is in state $\mathbf{x}$ at time t , R_k fires once in the time interval $[t, t + h)$. The propensity functions for elementary reactions is given in Table 1.

Limiting to the Deterministic Regime

There is an important connection between the stochastic process $X(t)$, as represented by the continuous-time discrete-state Markov chain described above, and the solution of a related deterministic reaction rate equations obtained from mass-action kinetics. To see this, let $\Phi(t) = [\Phi_1(t), \dots, \Phi_N(t)]^T$ be the vector concentrations of species $S_1, \dots, S_N$. According to mass-action kinetics, $\Phi(\cdot)$ satisfies the ordinary differential equation:

$$\dot{\Phi} = Sf(\Phi(t)), \quad \Phi(0) = \Phi_0.$$

In order to compare the $\Phi(t)$ with $X(t)$, which represents molecular counts, we divide $X(t)$ by the reaction volume to get $X^\Omega(t) = X(t)/\Omega$. It turns out that $X^\Omega(t)$ *limits* to $\Phi(t)$: According to Kurtz (Ethier and Kurtz 1986), for every $t \geq 0$:

$$\lim_{\Omega \rightarrow \infty} \sup_{s \leq t} |X^\Omega(s) - \Phi(s)| = 0, \quad \text{almost surely.}$$

Hence, over any finite time interval, the stochastic model *converges* to the deterministic mass-action one in the thermodynamic limit. Note that this is only a large volume limit result. In practice, for a fixed volume, a stochastic description may differ considerably from the deterministic description.

Stochastic Simulations

Gillespie's stochastic simulation algorithm (SSA) constructs sample paths for the random process $X(t) = (X_1(t) \dots X_N(t))^T$ that are consistent with the stochastic model described above (Gillespie 1976). It consists of the following basic steps:

1. Initialize the state $X(0)$ and set $t = 0$.
2. Draw a random number $\tau \in (0, \infty)$ with exponential distribution and mean equal to $1/\sum_k w_k(X(t))$.
3. Draw a random number $k \in \{1, 2, \dots, M\}$ such that the probability of $k = i \in \{1, 2, \dots, M\}$ is proportional to $w_i(X(t))$.
4. Set $X(t + \tau) = X(t) + s_k$ and $t = t + \tau$.
5. Repeat from (2) until t reaches the desired simulation time.

By running this algorithm multiple times with independent random draws, one can estimate the distribution and statistical moments of the random process $X(t)$.

The Chemical Master Equation (CME)

The *chemical master equation* (CME), also known as the forward Kolmogorov equation, describes the time evolution of the probability that the system is in a given state $\mathbf{x}$. The CME can be derived based on the Markov property of chemical reactions. Suppose the system is in state $\mathbf{x}$ at time t . Within an error of order $\mathcal{O}(h^2)$, the following statements apply:

- The probability that an R_k reaction fires exactly once in the time interval $[t, t + h)$ is given by $w_k(\mathbf{x})h$.

- The probability that no reactions fire in the time interval $[t, t + h)$ is given by $1 - \sum_k w_k(\mathbf{x})dx$.
- The probability that more than one reaction fires in the time interval $[t, t + h)$ is zero.

Let $P(\mathbf{x}, t)$, denote the probability that the system is in state $\mathbf{x}$ at time t . We can express $P(\mathbf{x}, t + h)$ as follows:

$$P(\mathbf{x}, t + h) = P(\mathbf{x}, t) \left(1 - \sum_k w_k(\mathbf{x})h \right) + \sum_k P(\mathbf{x} - \mathbf{s}_k, t) w_k(\mathbf{x} - \mathbf{s}_k)h + \mathcal{O}(h^2).$$

The first term on the right-hand side is the probability that the system is already in state $\mathbf{x}$ at time t , and no reactions occur in the next h . In the second term on the right-hand side, the k th term in the summation is the probability that the system at time t is an R_k reaction away from being at state $\mathbf{x}$ and that an R_k reaction takes place in the next h .

Moving $P(\mathbf{x}, t)$ to the left-hand side, dividing by h , and taking the limit as h goes to zero yields the chemical master equation (CME):

$$\frac{dP(\mathbf{x}, t)}{dt} = \sum_{k=1}^M \left(w_k(\mathbf{x} - \mathbf{s}_k) P(\mathbf{x} - \mathbf{s}_k, t) - w_k(\mathbf{x}) P(\mathbf{x}, t) \right). \quad (1)$$

The CME defines a linear dynamical system in the probabilities of the different states (each state is defined by a specific number of molecules of each of the species). However, there are generally an infinite number of states, and the resulting infinite linear system is not directly solvable. One approach to overcome this difficulty is to approximate the solution of the CME by truncating the states. A particular truncation procedure that gives error bounds is called the finite-state projection (FSP) (Munsky and Khammash 2006). The key idea behind the FSP approach is to keep those states that support the bulk of the probability distribution while projecting the remaining infinite states onto a single “absorbing” state. See Fig. 1.

The left panel in the figure shows the infinite states of a system with two species. The arrows indicate transitions among states caused by allowable chemical reactions. The underlying stochastic process is a continuous-time discrete-state Markov process. The right panel shows the projected (finite-state) system for a specific projection region (box). The projection is obtained

Stochastic Description of Biochemical Networks, Fig. 1 The finite-state projection

as follows: transitions within the retained states are kept, while transitions that emanate from these states and end at states outside the box are channeled to a single new absorbing state. Transitions into the box are deleted. The resulting projected system is a finite-state Markov process. The probability of each of its finite states can be computed exactly. It can be shown that the truncation, as defined here, gives a lower bound for the probability for the original full system. The FSP algorithm provides a way for constructing an approximation of the CME that satisfies any prespecified accuracy requirement.

Moment Dynamics

While the probability distribution $P(\mathbf{x}, t)$ provides great detail on the state $\mathbf{x}$ at time t , often statistical moments of the molecule copy numbers already provide important information about their variability, which motivates the construction of mathematical models for the evolution of such models over time.

Given a vector of integers $\mathbf{m} := (m_1, m_2, \dots, m_n)$, we use the notation $\mu^{(\mathbf{m})}$ to denote the following uncentered moment of X :

$$\mu^{(\mathbf{m})} := \mathbb{E}[X_1^{m_1} X_2^{m_2} \dots X_n^{m_n}].$$

Such moment is said to be of order $\sum_i m_i$. With N species, there are exactly N first-order moments $\mathbb{E}[X_i]$, $\forall i \in \{1, 2, \dots, N\}$, which are just the means; $N(N-1)/2$ second-order moments $\mathbb{E}[X_i^2]$, $\forall i$ and $\mathbb{E}[X_i X_j]$, $\forall i \neq j$, which can be used to compute variances and covariance; $N(N-1)(N-2)/6$ third-order moments; and so on.

Using the CME (1), one can show that

$$\begin{aligned} \frac{d\mu^{(\mathbf{m})}}{dt} = & \mathbb{E} \left[\sum_k w_k(X) \left((X_1 + s_{1,k})^{m_1} (X_2 - s_{2,k})^{m_2} \right. \right. \\ & \left. \left. \dots (X_N - s_{N,k})^{m_N} - X_1^{m_1} X_2^{m_2} \dots X_N^{m_N} \right) \right], \end{aligned}$$

and, because the propensity functions are all polynomials on $\mathbf{x}$ (cf. Table 1), the expected value in the right-hand side can actually be written as a

linear combination of other uncentered moments of X . This means that if we construct a vector μ containing all the uncentered moments of x up to some order k , the evolution of μ is determined by a differential equation of the form

$$\frac{d\mu}{dt} = A\mu + B\bar{\mu}, \quad \mu \in \mathbb{R}^K, \quad \bar{\mu} \in \mathbb{R}^{\bar{K}} \quad (2)$$

where A and B are appropriately defined matrices and $\bar{\mu}$ is a vector containing moments of order larger than k . The equation (2) is exact, and we call it the (*exact*) k -order moment dynamics, and the integer k is called the *order of truncation*. Note that the dimension K of (2) is always larger than k since there are many moments of each order. In fact, in general, K is of order n^k .

When all chemical reactions have only one reactant, the term $B\bar{\mu}$ does not appear in (2), and we say that the exact moment dynamics are *closed*. However, when at least one chemical reaction has two or more reactants, then the term $B\bar{\mu}$ appears, and we say that the moment dynamics are *open* since (2) depends on the moments in $\bar{\mu}$, which are not part of the state μ . When all chemical reactions are elementary (i.e., with at most two reactants), then all moments in $\bar{\mu}$ are exactly of order $k+1$.

Moment closure is a procedure by which one approximates the exact (but open) moment dynamics (2) by an approximate (but now closed) equation of the form

$$\dot{v} = Av + B\varphi(v), \quad v \in \mathbb{R}^K \quad (3)$$

where $\varphi(v)$ is a column vector that approximates the moments in $\bar{\mu}$. The function $\varphi(v)$ is called the moment closure function, and (3) is called the *approximate k th-order moment dynamics*. The goal of any moment closure method is to construct $\varphi(v)$ so that the solution v to (3) is close to the solution μ to (2).

There are three main approaches to construct the moment closure function $\varphi(\cdot)$:

1. *Matching-based methods* directly attempt to match the solutions to (2) and (3) (e.g., Singh and Hespanha 2011).

2. *Distribution-based methods* construct $\varphi(\cdot)$ by making reasonable assumptions on the statistical distribution of the molecule counts vector x (e.g., Gomez-Uribe and Verghese 2007).
3. *Large volume methods* construct $\varphi(\cdot)$ by assuming that reactions take place on a large volume (e.g., Van Kampen 2001).

It is important to emphasize that this classification is about methods to *construct* moment closure. It turns out that sometimes different methods lead to the same moment closure function $\varphi(\cdot)$.

Conclusion and Outlook

We have introduced complementary approaches to study the evolution of biochemical networks that exhibit important stochastic effects.

Stochastic simulations permit the construction of sample paths for the molecule counts, which can be averaged to study the ensemble behavior of the system. This type of approach scales well with the number of molecular species, but can be computationally very intensive when the number of reactions is very large. This challenge has led to the development of approximate stochastic simulation algorithms that attempt to simulate multiple reactions in the same simulation step (e.g., Rathinam et al. 2003).

Solving the CME provides the most detailed and accurate approach to characterize the ensemble properties of the molecular counts, but for most biochemical systems such solution cannot be found in closed form, and numerical methods scale exponentially with the number of species. This challenge has led to the development of algorithms that compute approximate solutions to the CME, e.g., by aggregating states with low probability, while keeping track of the error (e.g., Munsky and Khammash 2006).

Moment dynamics is attractive in that the number of k th-order moments only scales polynomially with the number of chemical species, but one only obtains closed dynamics for very simple biochemical networks. This limitation has led to the development of moment closure tech-

niques to approximate the open moment dynamics by a closed system of ordinary differential equations.

Stochastic Dynamic Programming

Qing Zhang

Department of Mathematics, The University of Georgia, Athens, GA, USA

Abstract

This article is concerned with one of the traditional approaches for stochastic control prob-

lems: Stochastic dynamic programming. Brief descriptions of stochastic dynamic programming methods and related terminology are provided. Two asset-selling examples are presented to illustrate the basic ideas. A list of topics and references are also provided for further reading.

Keywords

Asset-selling rule · Bellman equation · Hamilton-Jacobi-Bellman equation · Markov decision problem · Optimality principle · Stochastic control · Viscosity solution

Introduction

The term *dynamic programming* was introduced by Richard Bellman in the 1940s. It refers to a method for solving dynamic optimization problems by breaking them down into smaller and simpler subproblems.

To solve a given problem, one often needs to solve each part of the problem (subproblems) and then put together their solutions to obtain an overall solution. Some of these subproblems are of the same type. The idea behind the dynamic programming approach is to solve each subproblem only once in order to reduce the overall computation.

The cornerstone of dynamic programming (DP) is the so-called principle of optimality which is described by Bellman in his 1957 book (Bellman 1957):

Principle of Optimality: An optimal policy has the property that whatever the initial state and initial decision are, the remaining decisions must constitute an optimal policy with regard to the state resulting from the first decision.

This principle of optimality gives rise to DP (or optimality) equations, which are referred to as Bellman equations in discrete-time optimization problems or Hamilton-Jacobi-Bellman (HJB) equations in continuous-time ones. Such equations provide a necessary condition for optimality in terms of the value of the underlying decision problem. By and large, an optimal control policy

in most cases can be obtained by solving the associated Bellman (HJB) equation. In view of this, dynamic programming is a powerful tool for a broad range of control and decision-making problems. When the underlying system is driven by certain type of random disturbance, the corresponding DP approach is referred to as *stochastic dynamic programming*.

Terminology

The following concepts are often used in stochastic dynamic programming.

An **objective function** describes the objective of a given optimization problem (e.g., maximizing profits, minimizing cost, etc.) in terms of the states of the underlying system, decision (control) variables, and possible random disturbance.

State variables represent the information about the current system under consideration. For example, in a manufacturing system, one needs to know the current product inventory in order to decide how much to produce at the moment. In this case, the inventory level would be one of the state variables.

The variables chosen at any time are called the decision or **control variables**. For instance, the rate of production over time in the manufacturing system is a control variable. Typically, control variables are functions of state variables. They affect the future states of the system and the objective function.

In stochastic control problems, the system is also affected by random events (noise). Such noise is referred to system **disturbance**. The noise is often not available a priori. Only their probabilistic distributions are known.

The goal of the optimization problem is to choose control variables over time so as to either maximize or minimize the corresponding objective function. For example, in order to maximize the overall profits, a manufacturing firm has to decide how much to produce over time so as to maximize the revenue by meeting the product demand and minimize the costs associated with inventory. The best possible value of the objective

is called **value function**, which is given in terms of the state variables.

In the next two sections, we give two examples to illustrate how stochastic DP methods are used in discrete and continuous time.

An Asset-Selling Example (Discrete Time)

Consider a person wants to sell an asset (e.g., a car or a house). She is offered an amount of money every period (say, a day). Let $v_0, v_1, \dots, v_{N-1}$ denote the amount of these random offers. Assume they are independent and identically distributed. At the end of each period, the person has to decide whether to accept the offer or reject it. If she accepts the offer, she can put the money in a bank account and receive a fixed interest rate $r > 0$; if she rejects the offer, she waits till the next period. Rejected offers cannot be recycled. In addition, she has to sell her asset by the end of the N th period and accept the last offer v_{N-1} if all previous offers have been rejected. The goal is to decide when to accept an offer to maximize the overall return at the N th period.

In this example, for each k , v_k is the random disturbance. The control variables u_k take values in $\{\text{sell, hold}\}$. The state variables x_k are given by the equations

$$x_0 = 0; \quad x_{k+1} = \begin{cases} \text{sold} & \text{if } u_k = \text{sell} \\ v_k & \text{otherwise.} \end{cases}$$

Let

$$h_N(x_N) = \begin{cases} x_N & \text{if } x_N \neq \text{sold,} \\ 0 & \text{otherwise.} \end{cases}$$

$$h_k(x_k, u_k, v_k) = \begin{cases} (1+r)^{N-k}x_k & \text{if } x_k \neq \text{sold} \\ & \text{and } u_k = \text{sell} \\ 0 & \text{otherwise.} \end{cases}$$

for $k = 0, 1, \dots, N-1$.

Then, the payoff function is given by

$$E_{\{v_k\}} \left(h_N(x_N) + \sum_{k=0}^{N-1} h_k(x_k, u_k, v_k) \right).$$

Here, $E_{\{v_k\}}$ represents the expected value over $\{v_k\}$. The corresponding value functions $V_k(x_k)$ satisfy the following Bellman equations:

$$V_N(x_N) = \begin{cases} x_N & \text{if } x_N \neq \text{sold,} \\ 0 & \text{otherwise.} \end{cases}$$

$$V_k(x_k) = \begin{cases} \max \left((1+r)^{N-k}x_k, E V_{k+1}(v_k) \right) & \text{if } x_k \neq \text{sold} \\ 0 & \text{otherwise.} \end{cases}$$

for $k = 0, 1, \dots, N-1$.

The optimal selling rule can be given as (assuming $x_k \neq \text{sold}$) (see Bertsekas 1987):

accept the offer

$$v_{k-1} = x_k \text{ if } (1+r)^{N-k}x_k \geq E V_{k+1}(v_k),$$

reject the offer

$$v_{k-1} = x_k \text{ if } (1+r)^{N-k}x_k < E V_{k+1}(v_k).$$

Given the distribution for v_k , one can compute V_k backwards and solve the Bellman equations, which in turn leads to the above optimal selling rule.

Note that such backward iteration only works with finite horizon dynamic programming. When working with an infinite horizon (discounted or long-run average) payoff function, often used methods are value iteration (successive approxi-

mation) and policy iteration. The idea is to construct a sequence of functions recursively so that they converge pointwise to the value function. For description of these iteration methods, their convergence properties, and error bound analysis, we refer the reader to Bertsekas (1987).

Next, we consider a continuous-time asset-selling problem.

An Asset-Selling Example (Continuous Time)

Suppose a person wants to sell her asset. The price x_t at time $t \in [0, \infty)$ of her asset is given by a stochastic differential equation

$$\frac{dx_t}{x_t} = \mu dt + \sigma dw_t,$$

where μ and σ are known constants and w_t is the standard Brownian motion representing the disturbance. Suppose the transaction cost is K and the discount rate r . She has to decide when to sell her asset to maximize an expected return. In this example, the state variable is price x_t , control variable is a function of selling time τ , and the payoff function is given by

$$J(x, \tau) = Ee^{-r\tau}(x_\tau - K).$$

Let $V(x)$ denote the value function, i.e., $V(x) = \sup_\tau J(x, \tau)$. Then the associate HJB equation is given by

$$\min \left\{ rV(x) - x\mu \frac{dV(x)}{dx} - \frac{x^2\sigma^2}{2} \frac{d^2V(x)}{dx^2}, \right. \\ \left. V(x) - K \right\} = 0. \quad (1)$$

Let

$$x^* = \frac{K\beta}{\beta - 1},$$

where

$$\beta = \frac{1}{\sigma^2} \left(\frac{\sigma^2}{2} - \mu + \sqrt{\left(\mu - \frac{\sigma^2}{2} \right)^2 + 2r\sigma^2} \right).$$

Then the optimal selling rule can be given as (see Øksendal 2007):

$$\begin{cases} \text{sell} & \text{if } x_t \geq x^*, \\ \text{hold} & \text{if } x_t < x^*. \end{cases}$$

In general, to solve an optimal control problem via the DP approach, one first needs to solve the associate Bellman (HJB) equations. Then, these solutions can be used to come up with an optimal control policy. For example, in the above case, given the value function $V(x)$, one should hold if

$$rV(x) - x\mu \frac{dV(x)}{dx} - \frac{x^2\sigma^2}{2} \frac{d^2V(x)}{dx^2} = 0$$

and sell when $V(x) - K = 0$. The threshold level x^* is the exact dividing point between the first part equals zero and the second part vanishes. In addition, one can also provide a theoretical justification in terms of a verification theorem to show that the solution obtained this way is indeed optimal (see Fleming and Rishel (1975), Fleming and Soner (2006), or Yong and Zhou (1999)).

HJB Equation Characterization and Computational Methods

In continuous-time optimal control problem, one major difficulty that arises in solving the associated HJB equations (e.g., (1)) is the characterization of the solutions. In most cases, there is no guarantee that the derivatives or partial derivatives exist. In this connection, the concept of viscosity solutions developed by Crandall and Lions in the 1980s can often be used to characterize the solutions and their uniqueness. We refer the reader to Fleming and Soner (2006)

for related literature and applications. In addition, we would like to point out that closed-form solutions are rare in stochastic control theory and difficult to obtain in most cases. In many applications, one needs to resort to computational methods. One typical way to solve an HJB equation is the finite difference methods. An alternative is Kushner's Markov chain approximation methods; see Kushner and Dupuis (1992).

Summary and Future Directions

In this article, we have briefly stated stochastic DP methods, showed how they work in two simple examples, and discussed related issues. One serious limitation of the DP approach is the so-called curse of dimensionality. In other words, the DP does not work for problems with high dimensionality. Various efforts have been devoted to search for approximate solutions. One approach developed in recent years is the multi-time-scale approach. The idea is to classify random events according to the frequency of their occurrence. Frequent occurring events are grouped together and treated as a single "state" to achieve the reduction of dimensionality. We refer the reader to Yin and Zhang (2005, 2013) for related literature and theoretical development. Finally, we would like to mention that stochastic DP has been used in many applications in economics, engineering, management science, and finance. Some applications can be found in Sethi and Thompson (2000). Additional references are also provided at the end for further reading.

Abstract

This entry describes the state-of-the-art and future perspectives on stochastic fault detection, namely, stochastic fault detection and diagnosis (FDD). Both model-based and data-driven FDD methods for stochastic signals and systems have been included, where the use of hypothesis testing, Kalman filtering, system estimation, principal component analysis (PCA), and stochastic distribution control has been discussed for the construction of effective FDD algorithms. Indeed, stochastic FDD constitute an important and integrated part in developing fault-tolerant controls (FTC) for guaranteed safe operation of control systems, of which increased penetration of random factors is inevitable nowadays.

Introduction

Stochastic systems are everywhere. Examples are most of industrial processes, power grid, transportation systems, etc. For example, due to an increased penetration of renewables (wind, solar, and distributed energy storages, etc.) that are random in nature, control systems in power grid operation are now subjected to ever-increased degrees of randomness and uncertainties. This makes some grid key variables such as frequency, voltage, and power flow random and mostly even non-Gaussian. For industrial processes, the increased use of low-cost raw materials leads to large random variations and uncertainties in their compositions. This, together with variations of environments under which control systems operate, increases the degree of randomness for the whole system. During the operation of such systems, the effect of these random factors would inevitably affect their operational performance. As a result, system dynamics and most of the variables in these control systems exhibit stochastic nature.

For these systems, one of the important issues is its operational safety, and the challenge has always been how faults can be effectively detected and diagnosed so that proper actions can be taken to prevent the system from severe consequences caused by faults. In this regard, FDD play a key role. An earlier and accurate FDD can allow us to realize effective fault-tolerant control that ensures safe operation of the system after fault has occurred. In this context, FDD for stochastic systems have been studied for a long time and are still an important topic of research in the future.

Objective and General Structure

The objective of fault detection is to use available information such as various measured signals (data) from the system to detect the fault in the system, where the fault is regarded as unexpected changes during the system operation. Fault can happen in various parts of the system. It can be actuator, sensor, and system faults (Chen and Patton 2012; Isermann and Munchhof 2010). Also, it can be unexpected changes of statistics (mean and variance) of a signal or some system parameters (Basseville and Nikiforov 1993). Once fault is detected, fault diagnosis can be performed to find out its location and size. This defines the functionalities of FDD, which are applicable to any systems rather than just to stochastic systems. Here only stochastic systems and signals will be considered.

Since the system is stochastic in nature and the available information used for FDD are represented as random processes, tools such as hypothesis testing, filtering, system estimation, multivariable statistics, stochastic estimation theory, and stochastic distribution control have been developed in the past decades. These methods have been widely and successfully applied to perform FDD for stochastic systems.

In this regard, the following figure shows a generic structure of FDD for stochastic systems, where all the signals are function of time and some of them are random processes.

Using the notations in Fig. 1, the FDD for stochastic systems means to perform the following task:

$$\begin{aligned} & \text{Use } \{u(t), y(t), \text{other measured signals}\} \\ & \rightarrow \text{fault detection and diagnosis} \quad (1) \end{aligned}$$

The Existing Approaches

The earlier days of research in this area have largely been focused on developing algorithms for unexpected change detection of random signals and filtering-based fault detection and diagnosis for dynamic stochastic systems. The well-known Kalman filtering algorithms have been used to generate fault detection signals which can be used to activate an alarm when fault occurs. The idea is to use time-domain signals such as system inputs and outputs to constitute FDD algorithms (Fig. 1). Recently, further development has been seen for stochastic distribution systems, where FDD are performed using available system measurements on the probability

Stochastic Fault Detection, Fig. 1 A general structure for fault detection and diagnosis for stochastic systems

density functions (PDFs) of relevant system variables such as output PDFs of the concerned systems. In this section, survey on FDD for stochastic systems will be covered.

Model-Based Fault Detection for Stochastic Systems

To realize fast FDD, model-based approaches have been developed (Chen and Patton 2012; Isermann and Munchhof 2010) for systems of which their dynamic models can be established using first principles such as mass and energy balance laws. For the purpose of FDD, the availability of a healthy system dynamic model (i.e., fault-free model) is generally assumed, say, for example, the state space models subjected to random inputs or random parameter changes. Since the system is stochastic in nature, the dynamic model is either represented as a set of continuous stochastic differential equations (such as *Ito* differential equations) or discrete-time equations, and the model can be either in the state space or the input-output format.

State Space Model-Based Fault Detection and Diagnosis

When the system is in a state space form and is linear time-invariant, then the well-known Kalman filter techniques can be readily used to perform fault detection. In this case, one needs to construct a standard Kalman filter based upon the healthy state space model of the system and then monitors the changes of the “*residual signal*” of the filtering. Such a residual is taken as a testing signal for fault detection. Since the Kalman filter is constructed using healthy system parameters, if there is no fault occurring in the system, then the residual signal would quickly converge to a zero-mean Gaussian noise with minimum variance. This intuitively indicates that if the system has a fault, then the mean value of the residual of the Kalman filter will not be close to zero (Wang and Shang 2015; Villez et al. 2011). Therefore, to perform fault detection, the Kalman filter needs to operate online in parallel to the system. The monitoring of changes in the residual signal is required in line with the progression of time. For this purpose, a small threshold value is assigned

to monitor the residual. If the magnitude of the residual signal exceeds the threshold, then it can be concluded that there is a fault in the system. With reference to Fig. 1, this means that the following fault detection mechanism should apply

$$\begin{aligned} & \text{If } \|\varepsilon(t)\| > \delta \\ & \rightarrow \text{there is a fault in the system} \quad (2) \end{aligned}$$

where $\delta > 0$ is a pre-specified threshold. Once the system is claimed of faulty, fault diagnosis can be performed in order to find out where the fault has occurred and what its size is.

However, fault diagnosis is of much more complicated problem as its first stage is to estimate changes in model parameters. Therefore, in some case, the extended state space model is used by representing certain form of dynamics for unknown system parameters. In this way, the extended state vector is formed that consists of the original state vector and the model parameters to be estimated. As a result, the well-known Kalman filter can still be used for the extended state space model to simultaneously estimate the original state vector and the system parameters. Even so, there is also an issue to diagnose original faults in the system as the model parameters can be of a set of complicated nonlinear functions of the actual physical parameters whose unexpected changes reflect the actual faults in the system. Indeed, sometimes one physical parameter changes can lead to variations of several model parameters (Isermann and Munchhof 2010). Online inverse mapping between estimated model parameters and physical parameters is required in order to further estimate unexpected changes of physical parameters.

The Kalman filtering-based method constitutes a main structure in FDD for state space model represented stochastic systems. In case when system is nonlinear, the extended Kalman filtering or other types of filtering such as minimum entropy filtering (Guo et al. 2009) or particle filtering algorithms (Kadirkamanathan et al. 2002) can be used to formulate fault detection signals and fault diagnosis.

Input-Output Model-Based Fault Detection and Diagnosis

Rather than using the state space models, one can also use input-output models to detect and diagnose the fault in the system. For example, for linear time-invariant systems represented by autoregression and moving average with exogenous (ARMAX) models, one can directly use recursive system identification algorithms to perform simultaneous fault detection and diagnosis (Isermann and Munchhof 2010). Since the parameter identification directly estimates the changes of the model parameters in the system, it can give FDD results simultaneously. Of course, when the system is nonlinear, then the rather rich tools on nonlinear system estimation (i.e., maximum likelihood estimation, Bayesian estimation, neural networks, etc.) can be readily used to estimate system parameters from input and output measurements alone (Isermann and Munchhof 2010; Abreu and Gemund 2010). Again, fault diagnosis requires the use of the mapping between model and physical parameters, and the final fault diagnosis result is to obtain the estimation on the unexpected changes of physical parameters from the estimated model parameters.

Fault Detection and Diagnosis for Unknown Systems

When the healthy model of the system is not available, one needs to use system estimation techniques to establish a healthy model to start with from the measurements of the system input and output when there is no fault in the system. This requires the use of the first principle methods and data-driven techniques or a combination of both (i.e., gray box model or semi-physical modeling) to obtain healthy models for the system without faults. In many cases, neural networks and machine learning are used for such purposes. Once healthy models are obtained, FDD can be performed in the same way as we described before in sections “[State Space Model-Based Fault Detection and Diagnosis](#)” and “[Input-Output Model-Based Fault Detection and Diagnosis](#)”. In some cases, the learning of system healthy model and FDD needs to take place either at the same time or alternatively in the progression of

time in order to reduce the false alarm caused by either normal operational deterioration of system components or nominal external disturbances.

Data-Driven Fault Detection and Diagnosis for Stochastic Systems

Change Detection for Random Signals

Given a record of a signal embedded with random noises from a system, abrupt change detection is to find out whether there are some unexpected changes in such a signal in terms of its statistics such as mean value and variance (Basseville and Nikiforov 1993). This has been performed using hypothesis tests in statistics, where a testing signal is generated from the original signal. The hypothesis is either on *there is a change* or on *there is no change*. A threshold value is normally assigned to such an exercise. If the absolute value of testing signal is larger than the threshold, then it can be concluded that there is a change (or a fault) taking place in the system. This group of approaches come from a direct use of statistics theory and has shown to be effective in detecting faults reflected by a signal alone, rather than system models and dynamics. The algorithm is simple yet is slow in coping with fast fault detection for stochastic systems.

The Use of Principal Component Analysis (PCA) for Fault Detection and Diagnosis

Another group of FDD for stochastic systems is based upon a method in multivariable statistics theory called principal component analysis (PCA). The primary objective of PCA is to reduce the dimension of high-dimensional data column mostly seen in complex industrial processes (i.e., chemical plant, paper-making, steel-making, mineral processing plant, etc.). This requires effective analysis of “*big data*” so that operational characteristics of the process can be obtained and monitored. PCA can address challenges in terms of (1) analyzing directly a high-dimensional data (normally several hundreds to thousand channels of data) embedded with various random noises and (2) performing the required fault detection (or sometimes called “condition monitoring”) for the

process. Using PCA, such a high-dimensional data can be reduced into a small number of principal components – leading to the reduction of dimensionality in the sense that this small number of principal components can reflect most of the information and variabilities of the original fault-free high-dimensional data set. In this context, FDD can be carried out by monitoring “*residual vector*” changes when a new data set is collected using Hotelling’s and Q statistics (Bakshi 1998; Hong et al. 2011). This approach is powerful in fault detection and can be difficult sometimes in performing relevant fault diagnosis. Therefore, in some cases, a combination of PCA-based fault detection with model-based approach (such as filtering- or observer-based fault diagnosis) has been used.

Total Probabilistic Fault Detection and Diagnosis

Random processes are fully characterized by their probability density functions (PDFs) which evolves dynamically both in time and space for dynamic stochastic systems. With the fast development of sensing technology, nowadays, PDFs of some process variables can be measured online for some control processes seen in paper-making, combustion, transportation, and chemical plant. In this context, the research question is how one can use measured PDFs of the system variables (such as the output PDFs) to detect and diagnose the faults in the system. Different from traditional FDD where only time-domain signals are used, here, one needs to use input and output PDFs, which are functions of both time and space, to perform the required FDD. The following figure shows the structure of the FDD for this kind of systems, where $u(t)$ is the input, $\gamma(y, u)$ is the output PDFs, and y is the space variable that define the time-varying shape of output PDFs (Fig. 2).

This constitutes recent advances on FDD for stochastic distribution control systems. In this case, the output of such systems is represented by its time-varying PDFs, and the input is still a function of time.

This is largely a data-driven approach, where the system model is established when no fault

occurs using measured inputs and outputs PDFs (Wang 2000; Guo et al. 2009). Then by representing the output PDFs as a B-spline approximation with fixed set of basis functions, the approximation weights associated with basis functions can be represented as a standard state space form in the time domain. In this way, the parameter matrices of such a dynamical system can be estimated online using a series of measured output PDFs together with control inputs (Wang 2000). As a result, fault detection can be carried out using observer-based fault detection approaches well studied in the control systems research community. The only difference from the standard observer-based fault detection is that the residual for fault detection is formed using the functional distance concept with weighted integration of output PDFs. Once the fault is detected, it has been shown that fault diagnosis can be carried out using adaptive diagnostic observer in the same way as FDD for deterministic systems (Wang and Daley 1996; Chen and Patton 2012). In addition, FDD for stochastic distribution systems provide a theoretical foundation for designing image-based FDD as images captured from real systems (such as combustion flames images and traffic flow images) can be characterized by time-varying PDFs.

Stochastic Fault Detection, Fig. 2 Fault detection and diagnosis for stochastic distribution systems using output PDFs

Conclusions and Future Perspectives

In this entry, existing techniques on stochastic fault detection and diagnosis have been briefly described by generally grouping them as model-based and data-driven approaches. These approaches reflect the state of the art in this area and have been successfully applied to many control systems such as those seen in mechatronics systems, process industries, aerospace systems, etc. With the ever-increased complexity of control systems, stochastic FDD will continue to be an important topic of research for enhanced safe operation of systems. As a result, we have at least the following future perspectives:

(1) **Reliable fault detection and diagnosis:**

Since the system exhibits stochastic nature (where the signals used for FDD are random processes), highly reliable fault detection needs to be investigated to see how the fault can be detected and distinguished from normal variations of random variables. This will help to design a proper threshold that minimizes false alarm yet can still detect faults of small magnitudes in time. Moreover, fault diagnosis gives the location and size of the faults, which are calculated from measured samples of random signals such as system inputs and outputs. This indicates that the fault diagnosis that generates fault estimation signal is in fact a random process itself. Therefore, it is imperative that reliable fault diagnosis is produced with minimum randomness and high level of confidence. This also applies to fault prediction, where novel algorithms should be developed that can produce highly accurate prediction of the faults so that proactive fault-tolerant controls can be obtained.

(2) **Issues with large-scale systems:** For large-scale systems, FDD need to be carried out in a distributed way. This has been a subject of study in recent years and will still be one of the focused areas for stochastic FDD (Keliris et al. 2015; Boem et al.

2019). The key is to leverage the computing and communication capabilities for complex systems to construct distributed FDD. Once local faults are detected and diagnosed, it will be communicated to relevant system levels so that distributed and collaborative fault-tolerant control can be established.

- (3) **Resilience and cyber-security perspectives:** Resilience means a kind of “recovering” capability when the system is subjected to severe faults. It is therefore a special case of fault-tolerant controls. In parallel, by taking cyberattacks as faults to the system (e.g., unexpected changes in the set points for the control systems), then it also belongs to the scope of FDD for stochastic systems. Therefore, research into resilience and cyber-security issues need to use tools developed or to be developed for stochastic FDD. Novel methods are still needed to handle the faults in terms of enhanced resilience and cyber-security for issues on model representation and fast FDD.

Wrocław, Poland

Abstract

A stochastic game was introduced by Lloyd Shapley in the early 1950s. It is a dynamic game with *probabilistic transitions* played by one or more players. The game is played in a sequence of stages. At the beginning of

each stage, the game is in a certain *state*. The players select actions, and each player receives a *payoff* that depends on the current state and the chosen actions. The game then moves to a new random state whose distribution depends on the previous state and the actions chosen by the players. The procedure is repeated at the new state, and the play continues for a finite or infinite number of stages. The total payoff to a player is often taken to be the discounted sum of the stage payoffs or the limit inferior of the averages of the stage payoffs.

A learning problem arises when the agent does not know the reward function or the state transition probabilities. If an agent directly learns about its optimal policy without knowing either the reward function or the state transition function, such an approach is called *model-free reinforcement learning*. *Q-learning* is an example of such a model.

Q-learning has been extended to a noncooperative multi-agent context, using the framework of general-sum stochastic games. A learning agent maintains *Q*-functions over joint actions and performs updates based on assuming Nash equilibrium behavior over the current *Q*-values. The challenge is convergence of the learning protocol.

Introduction

A Stochastic Game

Definition 1 (Stochastic games) A stochastic game is a dynamic game with probabilistic transitions played by one or more players. The game is played in a sequence of stages. At the beginning of each stage, the game is in a certain state. The players select *actions*, and each player receives a *payoff* that depends on the current state and the chosen actions. The game then moves to

a new random state whose distribution depends on the previous state and the actions chosen by the players. The process is repeated at the new state, and the play continues for a finite or infinite number of stages.

The *total payoff* to a player can be defined in various ways. It depends on the payoffs at each stage and strategies chosen by players. The aim of the players is to control their total payoffs in the game by appropriate actions.

The notion of a stochastic game was introduced by Lloyd Shapley (1953) in the early 1950s. Stochastic games generalize both Markov decision processes (see also MDP) and repeated games. A repeated game is equivalent to a stochastic game with a single state. The stochastic game is played in discrete time with past history as common knowledge for all the players. An *individual strategy* for a player is a map which associates with each given history a probability distribution on the set of actions available to the players. The players' actions at stage n determine the players' payoffs at this stage and the state $s \in \mathcal{S}$ at stage $n + 1$.
